## 21. General Purpose Timer (TIM9/TIM12)

### 21.1 Introduction

The universal timers (TIM9 and TIM12) consist of a 16-bit auto-load counter driven by a programmable prescaler. It is suitable for a variety of uses, including measuring the pulse width of the input signal (input capture), or generating the output waveform (output comparison, PWM). Pulse lengths and waveform periods can be modulated from a few microseconds to several milliseconds using the timer prescaler and the RCC clock controller prescalers. The general purpose timers TIM9 and TIM12 are completely independent and they do not share any resources. They can be synchronized together.

#### 21.1.1 TIM9 and TIM12 Main Features

The functions of the TIM9 and TIM12 timers include:

- 16-bit up auto-load counter
- 16-bit programmable (can be modified in real time) prescaler, the frequency division coefficient of the counter clock frequency is any value between 1 and 65536
- Up to 2 independent channels:
  - Input capture
  - Output compare
  - PWM generation (edge alignment mode)
  - One-pulse mode output
- Synchronization circuit for controlling timer and interconnection between timer by external signal
- An interrupt occurs when the following events occur:
  - Update: Counter overflow, counter initialization (via software or internal trigger)
  - Trigger event (counter starts, stops, initializes, or counts by internal trigger)
  - Input capture
  - Output compare

### 21.1.2 CAN block diagram

## 21.2 TIM9/TIM12 functional description

### 21.2.1 Time-base unit

The main block of the programmable advanced-control timer is a 16-bit counter with its related auto-reload register. This counter can count up. The clock of the counter may be divided by a prescaler. The counter, the auto-reload register and the prescaler register can be written or read by software. This is true even when the counter is running.

The time base unit comprises:

- Counter Register (TIMx\_CNT)
- Prescaler Register (TIMx\_PSC)
- Autoload Register (TIMx\_ARR)

An autoloader register is preloaded, and a write or read autoloader register will access its preload register. The contents of the preload register are transferred to the shadow register either immediately or at each update event (UEV), depending on the setting of the Autoload preload enable bit (ARPE) in the TIMx\_CR1 register. An update event occurs when the counter reaches an overflow condition (overflow or underflow) and when the UDIS bit in the TIMx\_CR1 register is equal to 0. The update event may also be generated by software and other conditions. The generation of update events under each configuration will be described in detail later.

The counter is driven by the clock output CK\_CNT divided by the prescaler, which is valid for the counter only when the counter enable bit (CEN) in the TIMx\_CR1 register is set. (See the description of the slave mode controller for more details on enabling counters).

Note that the counter starts counting 1 clock cycle after setting the CEN bit in the TIMx\_CR register.

#### Prescaler description

The prescaler can divide the clock frequency of the counter by any value between 1 and 65536. It is a 16-bit counter controlled based on a 16-bit register (in the TIMx\_PSC register). It can be changed on

the fly as this control register is buffered. The new prescalation parameters will be adopted when the next update event comes.

The following figures give examples of changing counter parameters when the prescaler is running.

Figure 21-1 Timing diagram of the counter when the parameters of the prescaler change from 1 to 2

Figure 21-2 Timing diagram of the counter when the parameter of the prescaler is changed from 1 to 3

### 21.2.2 Counter mode

#### Upcounting mode

In the count-up mode, the counter counts from 0 to the auto-load value (the content of TIMx\_ARR), then counts from 0 again and generates a count overflow event.

Setting the UG bit in the TIMx\_EGR register (either by software or using a slave mode controller) can also generate an update event.

The UEV event can be disabled by software by setting the UDIS bit in the TIMx\_CR1 register. This is to avoid updating the shadow registers while writing new values in the preload registers. No update event will be generated until the UDIS bit is cleared '0'. Even so, when an update event should occur, the counter is still cleared '0', and the counter inside the prescaler is also cleared '0' (but the value of the prescaler remains unchanged).

In addition, if the URS bit in the TIMx\_CR1 register is set (select the update request source), an update event UEV can be generated by setting the UG bit, but the UIF flag bit will not be set (i.e., no interrupt request will be generated). This is to avoid generating both update and capture interrupts when clearing the counter on the capture event.

When an update event occurs, all of the following registers are updated, and the hardware sets an update flag bit (UIF bit in the TIMx\_SR register) at the same time (according to the URS bit):

- The auto-load shadow register is updated with the preload value (TIMx\_ARR).
- The buffer of the prescaler is reloaded with the preload value (content of the TIMx\_PSC register).

The following figures show some examples of the counter behavior for different clock frequencies when TIMx\_ARR=0x36.

Figure 21-3 counter timing diagram with internal clock division factor of 1

Figure 21-4 counter timing diagram with internal clock division factor of 2

Figure 21-5 Counter timing diagram, internal clock divided by 4

Figure 21-6 Counter timing diagram, internal clock divided by N

Figure 21-7 Counter timing diagram, update event when ARPE=0 (no TIMx\_ARR preloaded)

Figure 21-8 Counter timing diagram, update event when ARPE=1 (TIMx\_ARR preloaded)

### 21.2.3 Clock selection

The counter clock can be provided by the following clock sources:

- Internal clock (CK\_INT)
- External clock mode 1: External input pin (TIx)
- Internal Trigger Input (ITRx): Uses one timer as a prescaler for the other.

#### Internal clock source (CK\_INT)

If the slave mode controller is disabled (SMS = 000), the CEN and UG bits (TIMx\_EGR register) are de facto control bits and can only be modified by software (the UG bits are still automatically cleared). As long as the CEN bit is written as '1', the clock of the prescaler is provided by the internal clock CK\_INT.

The diagram below shows the operation of the control circuit and up counter in general mode, without the prescaler.

Figure 21-9 Control circuit in normal mode, internal clock divided by 1

#### External clock source mode 1

This mode is selected when SMS=111 in the TIMx\_SMCR register. The counter can count at each rising or falling edge on a selected input.

Figure 21-10 TI2 Example of external clock connection

For example, to configure the counter to count up on the rising edge of the TI2 input, use the following steps:

1. Configure channel 2 to detect rising edges on the TI2 input by writing CC2S = '01' in the TIMx\_CCMR1 register.
2. Configure IC2F [3: 0] of the TIMx\_CCMR1 register and select the input filter bandwidth (if no filter is needed, keep IC2F = 0000);
3. Select rising edge polarity by writing CC2P=0 in the TIMx\_CCER register.
4. Configure the timer in external clock mode 1 by writing SMS=111 in the TIMx\_SMCR register.
5. Select TI2 as the trigger input source by writing TS=00110 in the TIMx\_SMCR register;
6. Enable the counter by writing CEN=1 in the TIMx\_CR1 register.

Note: The capture prescaler is not used for triggering, so it does not need to be configured.

When a rising edge occurs on TI2, the counter counts once and the TIF flag is set.

The delay between the rising edge of TI2 and the actual clock of the counter depends on the synchronization circuit at the input of TI2.

Figure 21-11 Control circuit in external clock mode 1

#### 21.2.4 Capture/Compare channels

Each Capture/Compare channel is built around a capture/compare register (including a shadow register), an input stage for capture (with digital filter, multiplexing and prescaler) and an output stage (with comparator and output control).

The following figures are a capture/compare channel overview.

The input stage samples the corresponding TIx input to generate a filtered signal TIxF. An edge monitor with polarity selection then generates a signal (TIxFPx) that can be triggered as an input from the slave mode controller or as a capture control. It is prescaled before the capture register (ICxPS). It is prescaled before the capture register (ICxPS).

Figure 21-12 Capture/compare channel (example: channel 1 input stage)

The output stage generates an intermediate waveform which is then used for reference: OCxRef (active high). The polarity acts at the end of the chain.

Figure 21-13 Capture/Compare the main circuit of channel 1

Figure 21-14 Output stage of capture/compare channel

The capture/compare block is made of one preload register and one shadow register. Write and read always access the preload register.

In capture mode, captures are actually done in the shadow register, which is copied into the preload register.

In compare mode, the content of the preload register is copied into the shadow register which is compared to the counter.

### 21.2.5 Input capture mode:

In input capture mode, when the corresponding edge on the ICx signal is detected, the current value of the counter is latched into the capture/compare register (TIMx\_CCRx). When a capture event occurs, the corresponding CCxIF flag (TIMx\_SR register) is set to 1. If the CCxIF flag is already high when the capture event occurs, the over-capture flag CCxOF (TIMx\_SR register) is set to 1. The CCxIF can be cleared by writing CCxIF = 0, or by reading the captured data stored in the TIMx\_CCRx register. CCxOF is cleared when you write it to '0'.

The following example shows how to capture the counter value in TIMx\_CCR1 when TI1input rises. To do this, use the following procedure:

- Select valid input: TIMx\_CCMR1 must be connected to the TI1 input, so CC1S = 01 written in the TIMx\_CCMR1 register, as long as CC1S is not '00', the channel is configured as input, and the TIMx\_CCR1 register becomes read-only.
- Program the input filter duration you need with respect to the signal you connect to the timer (when the input is one of the TIx (ICxF bits in the TIMx\_CCMRx register)). Let's imagine that, when toggling, the input signal is not stable during at most 5 internal clock cycles. We must program a filter duration longer than these 5 clock cycles. We can validate a transition on TI1 when 8 consecutive samples with the new level have been detected (sampled at fDTS frequency). Then write IC1F bits to 0011 in the TIMx\_CCMR1 register.
- Select the valid transition edge of the TI1 channel and write CC1P = 0 (set to rising edge) in the TIMx\_CCER register.
- Program the input prescaler. In our example, we wish the capture to be performed at each valid transition, so the prescaler is disabled (write IC1PS bits to '00' in the TIMx\_CCMR1 register).
- Enable capture from the counter into the capture register by setting the CC1E bit in the TIMx\_CCER register.
- If desired, the associated interrupt request may be allowed by setting the CC1IE bit in the TIMx\_DIER register.

When an input capture occurs:

- The TIMx\_CCR1 register gets the value of the counter on the active transition.
- The CC1IF flag bit is set (interrupt flag). CC1OF is also set if at least two consecutive captures occurred whereas the flag was not cleared.
- An interrupt is generated depending on the CC1IE bit.

In order to handle the overcapture, it is recommended to read the data before the overcapture flag. This is to avoid missing an overcapture which could happen after reading the flag and before reading the data.

Note: IC interrupt can be generated by software by setting the corresponding CCxG bit in the TIMx\_EGR register.

### 21.2.6 PWM input mode

This mode is a special case of the input capture mode, and the rest of the operation is the same as the input capture mode except for the following differences:

- Both ICx signals are mapped to the same TIx input.
- These 2 ICx signals are active on edges with opposite polarity.
- One of the two TIxFP signals is selected as trigger input and the slave mode controller is configured in reset mode.

For example, the user can measure the cycle (TIMx\_CCR1 register) and the duty cycle (TIMx\_CCR2 register) of the PWM signal input to TI1 as follows

- Select the active input for TIMx\_CCR1: write the CC1S bits to 01 in the TIMx\_CCMR1 register (TI1 selected).
- Select the active polarity for TI1FP1 (used both for capture in TIMx\_CCR1 and counter clear): write the CC1P bit to '0' (active on rising edge).
- Select the active input for TIMx\_CCR2: write the CC2S bits to 10 in the TIMx\_CCMR1 register (TI1 selected).
- Select the active polarity for TI1FP2 (used for capture in TIMx\_CCR2): write the CC2Pbit to '1' (active on falling edge).
- Select the valid trigger input: write the TS bits to 101 in the TIMx\_SMCR register (TI1FP1 selected).
- Configure the slave mode controller in reset mode: write the SMS bits to 100 in the TIMx\_SMCR register.
- Enable the captures: write the CC1E and CC2E bits to '1' in the TIMx\_CCER register.

Figure 21-15 PWM input mode timing

Because only TI1FP1 and TI2FP2 are connected to the slave mode controller, the PWM input mode can only use the TIMx\_CH1/TIMx\_CH2 signal.

### 21.2.7 Forced output mode

In output mode (CCxS bits = 00 in the TIMx\_CCMRx register), each output compares signal(OCxREF and then OCx/OCxN) can be forced to active or inactive level directly by software, independently of any comparison between the output compare register and the counter.

To force an output compare signal (OCXREF/OCx) to its active level, you just need to write 101 in the OCxM bits in the corresponding TIMx\_CCMRx register. Thus OCXREF is forced high (OCxREF is always active high) and OCx get opposite value to CCxP polarity bit.

For example: CCxP=0 (OCx active high) => OCx is forced to high level.

The OCxREF signal can be forced low by writing the OCxM bits to 100 in the TIMx\_CCMRx register. Anyway, the comparison between the TIMx\_CCRx shadow register and the counter is still performed and allows the flag to be set. Interrupt can be sent accordingly. This is described in the output compare mode section below.

### 21.2.8 Output compare mode

This function is used to control an output waveform or indicate that a given period of time has expired. When a match is found between the capture/compare register and the counter, the output compare function:

- Assigns the corresponding output pin to a programmable value defined by the output compare mode (OCxM bits in the TIMx\_CCMRx register) and the output polarity (CCxP bit in the TIMx\_CCER register). The output pin can keep its level (OCxM=000), be set active (OCxM=001), be set inactive (OCxM=010) or can toggle (OCxM=011) on match.
- Sets a flag in the interrupt status register (CCxIF bit in the TIMx\_SR register).
- Generates an interrupt if the corresponding interrupt mask is set (CCXIE bit in the TIMx\_DIER register).

You can select whether the TIMx\_CCRx register needs to use a preload register by configuring the OCxPE bit in TIMx\_CCMRx.

In output compare mode, the update event UEV has no effect on OCxREF and OCx output. The timing resolution is one count of the counter. Output compare mode can also be used to output a single pulse (in One Pulse mode).

Procedure:

1. Select the counter clock (internal, external, prescaler).
2. Write the desired data in the TIMx\_ARR and TIMx\_CCRx registers.
3. Set the CCxIE bit if an interrupt request is to be generated.
4. Select the output mode. For example:
  - Write OCxM = 011 to toggle OCx output pin when CNT matches CCRx
  - Write OCxPE = 0 to disable preload register
  - Write CCxP = 0 to select active high polarity
  - Write CCxE = 1 to enable the output
5. Enable the counter by setting the CEN bit in the TIMx\_CR1 register.

The TIMx\_CCRx register can be updated by software at any time to control the output waveform, provided the preload register is not used (OCxPE = '0', otherwise the shadow register of TIMx\_CCRx can only be updated when the next update event occurs). An example is given in the figure below.

Figure 21-16 Output comparison mode, flip OC1

### 21.2.9 PWM mode

The pulse width modulation mode may produce a signal whose frequency is determined by the TIMx\_ARR register and whose duty cycle is determined by the TIMx\_CCRx register.

The OCxM bit in the TIMx\_CCMRx register is written to '110' (PWM mode 1) or '111' (PWM mode 2), and each OCx output channel can be independently set to generate a PWM. The corresponding preload register must be enabled by setting the OCxPE bit of the TIMx\_CCMRx register, and finally the ARPE bit of the TIMx\_CR1 register to enable the auto-reload preload register.

The preload register can only be transferred to the shadow register when an update event occurs, so the user must initialize all registers by setting the UG bit in the TIMx\_EGR register before the counter starts counting.

OCx polarity is software programmable using the CCxP bit in the TIMx\_CCER register. It can be programmed as active high or active low. The output of OCx is enabled by CCxE control (in TIMx\_CCER). Refer to the TIMx\_CCER register description for more details.

In PWM mode (1 or 2), TIMx\_CNT and TIMx\_CCRx are always compared to determine whether  $TIMx\_CCRx \leq TIMx\_CNT$  or  $TIMx\_CNT \leq TIMx\_CCRx$  (depending on the direction of the counter).

#### PWM edge-aligned mode

##### ■ Upcounting configuration

In the following example, we consider PWM mode 1. The reference PWM signal OCxREF is high as long as  $TIMx\_CNT < TIMx\_CCRx$  else it becomes low. If the comparison value in TIMx\_CCRx is greater than the auto-reload value (TIMx\_ARR), OCxREF remains '1'. If the comparison value is 0, then OCxREF remains '0'. Figure below shows some edge-aligned PWM waveforms in an example where TIMx\_ARR=8.

Figure 21-17 Edge-aligned PWM waveforms (ARR=8)

### 21.2.10 One-pulse mode

One-pulse mode (OPM) is a particular case of the previous modes. It allows the counter to be started in response to a stimulus and to generate a pulse with a programmable length after a programmable delay.

Starting the counter can be controlled through the slave mode controller. Generating the waveform can be done in output compare mode or PWM mode. One-pulse mode is selected by setting the OPM bit in the TIMx\_CR1 register. This makes the counter stop automatically at the next update event UEV. A pulse can be correctly generated only if the compare value is different from the counter initial value. Before starting (when the timer is waiting for the trigger), the configuration must be:

- Up count mode: counter  $CNT < CCRx \leq ARR$  (in particular,  $0 < CCRx$ ),

Figure 21-18 Example of one pulse mode

For example one may want to generate a positive pulse on OC1 with a length of  $t_{PULSE}$  and after a delay of  $t_{DELAY}$  as soon as a positive edge is detected on the TI2 input pin.

Assume TI2FP2 as the trigger:

- Map TI2FP2 on TI2 by writing  $CC2S=01$  in the TIMx\_CCMR1 register.
- TI2FP2 must detect a rising edge, write  $CC2P=0$  in the TIMx\_CCER register.
- Configure TI2FP2 as trigger for the slave mode controller (TRGI) by writing  $TS=110$  in the

TIMx\_SMCR register.

- TI2FP2 is used to start the counter by writing SMS to '110' in the TIMx\_SMCR register (trigger mode).

The OPM waveform is defined by writing the compare registers (taking into account the clock frequency and the counter prescaler).

- The tDELAY is defined by the value written in the TIMx\_CCR1 register.
- The tPULSE is defined by the difference between the auto-reload value and the compare value (TIMx\_ARR - TIMx\_CCR1).
- Let's say one want to build a waveform with a transition from '0' to '1' when a compare match occurs and a transition from '0' to '1' when the counter reaches the auto-reload value. To do this PWM mode 2 must be enabled by writing OC1M=111 in the TIMx\_CCMR1 register. Optionally the preload registers can be enabled by writing OC1PE='1' in the TIMx\_CCMR1 register and ARPE in the TIMx\_CR1 register. In this case one has to write the compare value in the TIMx\_CCR1 register, the auto-reload value in the TIMx\_ARR register, generate an update by setting the UG bit and wait for external trigger event on TI2. CC1P is written to '0' in this example.

Since only 1 pulse (Single mode) is needed, a 1 must be written in the OPM bit in the TIMx\_CR1 register to stop the counter at the next update event (when the counter rolls over from the auto-reload value back to 0)

#### 21.2.10.1 Particular case: OCx fast enable:

In One-pulse mode, the edge detection on TIx input set the CEN bit which enables the counter. Then the comparison between the counter and the compare value makes the output toggle. But several clock cycles are needed for these operations, and it limits the minimum delay tDELAY min we can get. If one wants to output a waveform with the minimum delay, the OCxFE bit can be set in the TIMx\_CCMRx register. Then OCxREF (and OCx) is forced in response to the stimulus, without taking in account the comparison. Its new level is the same as if a compare match had occurred. OCxFE acts only if the channel is configured in PWM1 or PWM2mode.

#### 21.2.11 Synchronization of TIMx timer and externally triggered

The TIMx timer can be synchronized with an external trigger in multiple modes: reset mode, gated mode, trigger mode.

##### 21.2.11.1 Slave mode: Reset mode

When a trigger input event occurs, the counter and its prescaler can be re-initialized; Meanwhile, if the UDIS bit of the TIMx\_CR1 register is low, an update event UEV is also generated; All preload registers (TIMx\_ARR, TIMx\_CCRx) are then updated.

In the following example, the upcounter is cleared in response to a rising edge on TI1 input:

- Configure the channel 1 to detect rising edges on TI1. Configure the input filter duration (in this example, we do not need any filter, so we keep IC1F=0000). The capture prescaler is not used for triggering, so it does not need to be configured. The CC1S bits select the input capture source only, CC1S=01 in TIMx\_CCMR1 register. Write CC1P=0 in TIMx\_CCER register to validate the polarity (and detect rising edges only).
- Configure the timer in reset mode by writing SMS=100 in TIMx\_SMCR register. Select TI1 as the

input source by writing TS=00101 in TIMx\_SMCR register.

- Enable the counter by writing CEN=1 in the TIMx\_CR1 register.

The counter starts counting on the internal clock, then behaves normally until TI1 rising edge. When TI1 rises, the counter is cleared and restarts from 0. At the same time, the trigger flag (TIF bit in the TIMx\_SR register) is set, and the following figure shows the action when the auto-reload register TIMx\_ARR = 0x36. The delay between the rising edge on TI1 and the actual reset of the counter is due to the resynchronization circuit on TI1 input.

Figure 21-19 Control circuit in reset mode

#### 21.2.11.2 Slave mode: Gated mode

The counter can be enabled depending on the level of a selected input.

In the following example, the upcounter counts only when TI1 input is low:

- Configure the channel 1 to detect low levels on TI1. Configure the input filter duration (in this example, we do not need any filter, so we keep IC1F=0000). The capture prescaler is not used for triggering, so it does not need to be configured. The CC1S bits select the input capture source only, CC1S=01 in TIMx\_CCMR1 register. Write CC1P=1 in TIMx\_CCER register to validate the polarity (and detect low level only).
- Configure the timer in gated mode by writing SMS=101 in TIMx\_SMCR register. Select TI1 as the input source by writing TS=00101 in TIMx\_SMCR register.
- Enable the counter by writing CEN=1 in the TIMx\_CR1 register. In gated mode, the counter doesn't start if CEN=0, whatever is the trigger input level.

The counter starts counting on the internal clock as long as TI1 is low and stops as soon as TI1 becomes high. The TIF flag in the TIMx\_SR register is set both when the counter starts or stops.

The delay between the rising edge on TI1 and the actual stop of the counter is due to the resynchronization circuit on TI1 input.

Figure 21-20 Control circuit in Gated mode

### 21.2.11.3 Slave mode: Trigger mode

The selected event on the input enables the counter.

In the following example, the upcounter starts in response to a rising edge on TI2 input:

- Configure the channel 2 to detect rising edges on TI2. Configure the input filter duration (in this example, we do not need any filter, so we keep IC2F=0000). The capture prescaler is not used for triggering, so it does not need to be configured. The CC2S bits are configured to select the input capture source only, CC2S=01 in TIMx\_CCMR1 register. Write CC2P=1 in TIMx\_CCER register to validate the polarity (and detect low level only).
- Configure the timer in trigger mode by writing SMS=110 in TIMx\_SMCR register. Select TI2 as the input source by writing TS=00110 in TIMx\_SMCR register.

When a rising edge occurs on TI2, the counter starts counting on the internal clock and the TIF flag is set.

The delay between the rising edge on TI2 and the actual start of the counter is due to the resynchronization circuit on TI2 input.

Figure 21-21 Control circuit in trigger mode

### 21.2.12 Timer synchronization

The TIMx timers are linked together internally for timer synchronization or chaining. See Section 20.2.22: Timer Synchronization for details.

### 21.2.13 Debug mode

When the microcontroller enters the debug mode (Cortex-M4F core stops), the TIMx counter may either continue normal operation or stop according to the setting of DBG\_TIMx\_STOP in the DBG module. See subsequent DBG sections for details.

## 22. General Purpose Timer

### (TIM10/TIM11/TIM13/TIM14/TIM19)

#### 22.1 Introduction

The general purpose timer (TIM10/TIM11/TIM13/TIM14/TIM19, hereinafter referred to as TIMx) consists of a 16-bit auto-load counter driven by a programmable prescaler. It is suitable for a variety of uses, including measuring the pulse width of the input signal (input capture), or generating the output waveform (output comparison, PWM). Pulse lengths and waveform periods can be modulated from a few microseconds to several milliseconds using the timer prescaler and the RCC clock controller prescalers. Universal timers (TIMx) are completely independent, they do not share any resources. They can be synchronized together.

##### 22.1.1 TIMx Main Features

The functions of the TIMx timer include:

- 16-bit up auto-load counter
- 16-bit programmable (can be modified in real time) prescaler, the frequency division coefficient of the counter clock frequency is any value between 1 and 65536
- 1 independent channel:
  - Input capture
  - Output compare
  - PWM generation (edge mode)
  - One-pulse mode output
- An interrupt occurs when the following events occur:
  - Counter overflow, counter initialization (via software)
  - Input capture
  - Output compare

### 22.1.2 CAN block diagram

## 22.2 TIMx functional description

### 22.2.1 Time-base unit

The main block of the programmable advanced-control timer is a 16-bit counter with its related auto-reload register. This counter can count up. The clock of the counter may be divided by a prescaler. The counter, the auto-reload register and the prescaler register can be written or read by software. This is true even when the counter is running.

The time base unit comprises:

- Counter Register (TIMx\_CNT)
- Prescaler Register (TIMx\_PSC)
- Autoload Register (TIMx\_ARR)

An autoloader register is preloaded, and a write or read autoloader register will access its preload register. The contents of the preload register are transferred to the shadow register either immediately or at each update event (UEV), depending on the setting of the Autoload preload enable bit (ARPE) in the TIMx\_CR1 register. An update event occurs when the counter reaches an overflow condition and when the UDIS bit in the TIMx\_CR1 register is equal to 0. The update event may also be generated by software and other conditions.

The counter is driven by the clock output CK\_CNT divided by the prescaler, which is valid for the counter only when the counter enable bit (CEN) in the TIMx\_CR1 register is set.

Note that the counter starts counting 1 clock cycle after setting the CEN bit in the TIMx\_CR register.

#### Prescaler description

The prescaler can divide the clock frequency of the counter by any value between 1 and 65536. It is a 16-bit counter controlled based on a 16-bit register (in the TIMx\_PSC register). It can be changed on the fly as this control register is buffered. The new prescalation parameters will be adopted when the next update event comes.

The following figures give examples of changing counter parameters when the prescaler is running.

Figure 22-1 Timing diagram of the counter when the parameters of the prescaler change from 1 to 2

Figure 22-2 Timing diagram of the counter when the parameter of the prescaler is changed from 1 to 4

### 22.2.2 Counter mode

#### Upcounting mode

In the count-up mode, the counter counts from 0 to the auto-load value (the content of TIMx\_ARR), then counts from 0 again and generates a count overflow event.

Setting the UG bit in the TIMx\_EGR register (either by software or using a slave mode controller) can also generate an update event.

The UEV event can be disabled by software by setting the UDIS bit in the TIMx\_CR1 register. This is to avoid updating the shadow registers while writing new values in the preload registers. No update event will be generated until the UDIS bit is cleared '0'. Even so, when an update event should occur,

the counter is still cleared '0', and the counter inside the prescaler is also cleared '0' (but the value of the prescaler remains unchanged).

In addition, if the URS bit in the TIMx\_CR1 register is set (select the update request source), an update event UEV can be generated by setting the UG bit, but the UIF flag bit will not be set (i.e., no interrupt request will be generated). This is to avoid generating both update and capture interrupts when clearing the counter on the capture event.

When an update event occurs, all of the following registers are updated, and the hardware sets an update flag bit (UIF bit in the TIMx\_SR register) at the same time (according to the URS bit):

- The auto-load shadow register is updated with the preload value (TIMx\_ARR).
- The buffer of the prescaler is reloaded with the preload value (content of the TIMx\_PSC register).

The following figures show some examples of the counter behavior for different clock frequencies when TIMx\_ARR=0x36.

Figure 22-3 counter timing diagram with internal clock division factor of 1

Figure 22-4 counter timing diagram with internal clock division factor of 2

Figure 22-5 Counter timing diagram, internal clock divided by 4

Figure 22-6 Counter timing diagram, internal clock divided by N

Figure 22-7 Counter timing diagram, update event when ARPE=0 (no TIMx\_ARR preloaded)

Figure 22-8 Counter timing diagram, update event when ARPE=1 (TIMx\_ARR preloaded)

### 22.2.3 Clock selection

The counter clock can be provided by the following clock sources:

- Internal clock (CK\_INT)

#### Internal clock source (CK\_INT)

For TIM10/TIM11/TIM13/TIM14/TIM19, the internal clock source is the default clock, then the CEN and UG bits (TIMx\_EGR registers) are de facto control bits and can only be modified by software (the UG bits are still automatically cleared). As long as the CEN bit is written as '1', the clock of the prescaler is provided by the internal clock CK\_INT.

The diagram below shows the operation of the control circuit and up counter in general mode, without the prescaler.

Figure 22-9 Control circuit in normal mode, internal clock divided by 1

### 22.2.4 Capture/Compare channels

Each Capture/Compare channel is built around a capture/compare register (including a shadow register), an input stage for capture (with digital filter, multiplexing and prescaler) and an output stage (with comparator and output control).

The following figures are capture/compare channel overviews.

The input stage samples the corresponding TIx input to generate a filtered signal TIxF. An edge monitor with polarity selection then produces a signal (TIxFPx), which can be used as a capture control. It is prescaled before the capture register (ICxPS).

Figure 22-10 capture channel

The output stage generates an intermediate waveform which is then used for reference: OCxRef (active high). The polarity acts at the end of the chain.

Figure 22-11 Capture/Compare the main circuit of channel 1

Figure 22-12 Output stage of capture/compare channel

The capture/compare block is made of one preload register and one shadow register. Write and read always access the preload register.

In capture mode, captures are actually done in the shadow register, which is copied into the preload register.

In compare mode, the content of the preload register is copied into the shadow register which is compared to the counter.

### 22.2.5 Input capture mode:

In input capture mode, when the corresponding edge on the ICx signal is detected, the current value of the counter is latched into the capture/compare register (TIMx\_CCRx). When a capture event occurs, the corresponding CCxIF flag (TIMx\_SR register) is set to 1. If the CCxIF flag is already high when the capture event occurs, the over-capture flag CCxOF (TIMx\_SR register) is set to 1. The CCxIF can be cleared by writing CCxIF = 0, or by reading the captured data stored in the TIMx\_CCRx register. CCxOF is cleared when you write it to '0'.

The following example shows how to capture the counter value in TIMx\_CCR1 when TI1input rises. To do this, use the following procedure:

- Select valid input: TIMx\_CCMR1 must be connected to the TI1 input, so CC1S = 01 written in the TIMx\_CCMR1 register, as long as CC1S is not '00', the channel is configured as input, and the TIMx\_CCR1 register becomes read-only.
- Program the input filter duration you need with respect to the signal you connect to the timer (when the input is one of the TIx (ICxF bits in the TIMx\_CCMRx register)). Let's imagine that, when toggling, the input signal is not stable during at most 5 internal clock cycles. We must program a filter duration longer than these 5 clock cycles. We can validate a transition on TI1 when 8 consecutive samples with the new level have been detected (sampled at fDTS frequency). Then write IC1F bits to 0011 in the TIMx\_CCMR1 register.
- Select the valid transition edge of the TI1 channel and write CC1P = 0 (set to rising edge) in the TIMx\_CCER register.
- Program the input prescaler. In our example, we wish the capture to be performed at each valid transition, so the prescaler is disabled (write IC1PS bits to '00' in the TIMx\_CCMR1 register).
- Enable capture from the counter into the capture register by setting the CC1E bit in the TIMx\_CCER register.
- If desired, the associated interrupt request may be allowed by setting the CC1IE bit in the

TIMx\_DIER register.

When an input capture occurs:

- The TIMx\_CCR1 register gets the value of the counter on the active transition.
- The CC1IF flag bit is set (interrupt flag). CC1OF is also set if at least two consecutive captures occurred whereas the flag was not cleared.
- An interrupt is generated depending on the CC1IE bit.

In order to handle the overcapture, it is recommended to read the data before the overcapture flag. This is to avoid missing an overcapture which could happen after reading the flag and before reading the data.

Note: IC interrupt can be generated by software by setting the corresponding CCxG bit in the TIMx\_EGR register.

### 22.2.6 Forced output mode

In output mode (CCxS bits = 00 in the TIMx\_CCMRx register), each output compares signal(OCxREF and then OCx/OCxN) can be forced to active or inactive level directly by software, independently of any comparison between the output compare register and the counter.

To force an output compare signal (OCXREF/OCx) to its active level, you just need to write 101 in the OCxM bits in the corresponding TIMx\_CCMRx register. Thus OCXREF is forced high (OCxREF is always active high) and OCx get opposite value to CCxP polarity bit.

For example: CCxP=0 (OCx active high) => OCx is forced to high level.

The OCxREF signal can be forced low by writing the OCxM bits to 100 in the TIMx\_CCMRx register. Anyway, the comparison between the TIMx\_CCRx shadow register and the counter is still performed and allows the flag to be set. Interrupt can be sent accordingly. This is described in the output compare mode section below.

### 22.2.7 Output compare mode

This function is used to control an output waveform or indicate that a given period of time has expired. When a match is found between the capture/compare register and the counter, the output compare function:

- Assigns the corresponding output pin to a programmable value defined by the output compare mode (OCxM bits in the TIMx\_CCMRx register) and the output polarity (CCxP bit in the TIMx\_CCER register). The output pin can keep its level (OCXM=000), be set active (OCxM=001), be set inactive (OCxM=010) or can toggle (OCxM=011) on match.
- Sets a flag in the interrupt status register (CCxIF bit in the TIMx\_SR register).
- Generates an interrupt if the corresponding interrupt mask is set (CCXIE bit in the TIMx\_DIER register).

You can select whether the TIMx\_CCRx register needs to use a preload register by configuring the OCxPE bit in TIMx\_CCMRx.

In output compare mode, the update event UEV has no effect on OCxREF and OCx output. The timing resolution is one count of the counter. Output compare mode can also be used to output a single pulse (in One Pulse mode).

Procedure:

1. Select the counter clock (internal, prescaler).
2. Write the desired data in the TIMx\_ARR and TIMx\_CCRx registers.
3. Set the CCxIE bit if an interrupt request is to be generated.
4. Select the output mode. For example:
  - Write OCxM = 011 to toggle OCx output pin when CNT matches CCRx
  - Write OCxPE = 0 to disable preload register
  - Write CCxP = 0 to select active high polarity
  - Write CCxE = 1 to enable the output
5. Enable the counter by setting the CEN bit in the TIMx\_CR1 register.

The TIMx\_CCRx register can be updated by software at any time to control the output waveform, provided the preload register is not used (OCxPE = '0', otherwise the shadow register of TIMx\_CCRx can only be updated when the next update event occurs). An example is given in the figure below.

Figure 22-13 Output comparison mode, flip OC1

### 22.2.8 PWM mode

The pulse width modulation mode may produce a signal whose frequency is determined by the TIMx\_ARR register and whose duty cycle is determined by the TIMx\_CCRx register.

The OCxM bit in the TIMx\_CCMRx register is written to '110' (PWM mode 1) or '111' (PWM mode 2), and each OCx output channel can be independently set to generate a PWM. The corresponding preload register must be enabled by setting the OCxPE bit of the TIMx\_CCMRx register, and finally setting the ARPE bit of the TIMx\_CR1 register to enable the preload register that can be automatically reloaded.

The preload register can only be transferred to the shadow register when an update event occurs, so the user must initialize all registers by setting the UG bit in the TIMx\_EGR register before the counter starts counting.

OCx polarity is software programmable using the CCxP bit in the TIMx\_CCER register. It can be programmed as active high or active low. The output of OCx enables control by the CCxE bit (in TIMx\_CCER). Refer to the TIMx\_CCER register description for more details.

In PWM mode (1 or 2), TIMx\_CNT and TIMx\_CCRx are always compared to determine whether  $\text{TIMx\_CCRx} \leq \text{TIMx\_CNT}$  or  $\text{TIMx\_CNT} \leq \text{TIMx\_CCRx}$  (depending on the direction of the counter).

## PWM edge-aligned mode

### ■ Upcounting configuration

In the following example, we consider PWM mode 1. The reference PWM signal OCxREF is high as long as  $TIMx\_CNT < TIMx\_CCRx$  else it becomes low. If the comparison value in  $TIMx\_CCRx$  is greater than the auto-reload value ( $TIMx\_ARR$ ), OCxREF remains '1'. If the comparison value is 0, then OCxREF remains '0'. Figure below shows some edge-aligned PWM waveforms in an example where  $TIMx\_ARR=8$ .

Figure 22-14 Edge-aligned PWM waveforms (ARR=8)

### 22.2.9 One-pulse mode

One-pulse mode (OPM) is a particular case of the previous modes. It allows the counter to be started in response to a stimulus and to generate a pulse with a programmable length after a programmable delay.

Since only 1 pulse (Single mode) is needed, a 1 must be written in the OPM bit in the  $TIMx\_CR1$  register to stop the counter at the next update event (when the counter rolls over from the auto-reload value back to 0)

### 22.2.10 Timer synchronization

The  $TIMx$  timers are linked together internally for timer synchronization or chaining. See Section 20.2.22: Timer Synchronization for details.

### 22.2.11 Debug mode

When the microcontroller enters debug mode (Cortex-M4F core stops), according to the setting of  $DBG\_TIMx\_STOP$  in the DBG module,

The  $TIMx$  counter may either continue normal operation or stop. See subsequent DBG sections for details.

## 23. General Purpose Timer (TIM15/TIM16/TIM17)

### 23.1 Introduction

The universal control timer (TIM15\_16\_17) consists of a 16-bit auto-load counter driven by a programmable prescaler. It may be used for a variety of purposes, including measuring the pulse lengths of input signals (input capture) or generating output waveforms (output compare, PWM, complementary PWM with dead-time insertion). Pulse lengths and waveform periods can be modulated from a few microseconds to several milliseconds using the timer prescaler and the RCC clock controller prescalers. The universal control timer (TIM15\_16\_17) and the universal timer (TIMx) are completely independent and do not share any resources. They can be synchronized together.

#### 23.1.1 TIM15 features

The functions of the TIM15 timer include:

- 16-bit up auto-load counter
- 16-bit programmable (can be modified in real time) prescaler, the frequency division coefficient of the counter clock frequency is any value between 1 and 65536
- Up to 2 independent channels:
  - Input capture
  - Output compare
  - PWM generation (edge alignment mode)
  - One-pulse mode output
- Complementary output with programmable dead time (channel 1 only)
- Synchronization circuit for controlling timer and interconnection between timer by external signal
- Allows the repetition counter of the timer register to be updated after a specified number of counter cycles
- The brake input signal may place the timer output signal into a reset state or a known state
- An interrupt/DMA occurs when the following events occur:
  - Update: Counter overflow, counter initialization (via software or internal/external trigger)
  - Trigger event (counter starts, stops, initializes or counts by internal/external triggers)
  - Input capture
  - Output compare
  - Brake signal input

### 23.1.2 CAN block diagram

### 23.1.3 TIM16\_17 features

The functions of the TIM16\_17 timer include:

- 16-bit up, down, up/down auto load counter
- 16-bit programmable (can be modified in real time) prescaler, the frequency division coefficient of the counter clock frequency is any value between 1 and 65536
- 1 independent channel:
  - Input capture
  - Output compare
  - PWM generation (edge alignment mode)
  - One-pulse mode output
- Complementary output with programmable dead time
- Allows the repetition counter of the timer register to be updated after a specified number of counter cycles
- The brake input signal may place the timer output signal into a reset state or a known state
- An interrupt/DMA occurs when the following events occur:
  - Counter overflows up
  - Input capture
  - Output compare
  - Brake signal input

### 23.1.4 CAN block diagram

## 23.2 TIM15\_16\_17 functional description

### 23.2.1 Time-base unit

The main block of the programmable advanced-control timer is a 16-bit counter with its related auto-reload register. The clock of the counter may be divided by a prescaler.

The counter, the auto-reload register and the prescaler register can be written or read by software. This is true even when the counter is running.

The time base unit comprises:

- Counter Register (TIMx\_CNT)
- Prescaler Register (TIMx\_PSC)
- Automoal Register (TIMx\_ARR)
- Repetition Register (TIMx\_RCR)

An autoloal register is preloaded, and a write or read autoloal register will access its preload register. The contents of the preload register are transferred to the shadow register either immediately or at each update event (UEV), depending on the setting of the Automoal preload enable bit (ARPE) in the TIMx\_CR1 register. An update event occurs when the counter reaches an overflow condition (overflow or underflow) and when the UDIS bit in the TIMx\_CR1 register is equal to 0. The update event may also be generated by software and other conditions. The generation of update events under each configuration will be described in detail later.

The counter is driven by the clock output CK\_CNT divided by the prescaler, which is valid for the counter only when the counter enable bit (CEN) in the TIMx\_CR1 register is set. (See the description of the slave mode controller for more details on enabling counters).

Note that the counter starts counting 1 clock cycle after setting the CEN bit in the TIMx\_CR register.

### Prescaler description

The prescaler can divide the clock frequency of the counter by any value between 1 and 65536. It is a 16-bit counter controlled based on a 16-bit register (in the TIMx\_PSC register). It can be changed on the fly as this control register is buffered. The new prescalation parameters will be adopted when the next update event comes.

The following figures give examples of changing counter parameters when the prescaler is running.

Figure 23-1 Timing diagram of the counter when the parameters of the prescaler change from 1 to 2

Figure 23-2. Timing diagram of the counter when the parameter of the prescaler is changed from 1 to 4

### 23.2.2 Counter mode

#### Upcounting mode

In the count-up mode, the counter counts from 0 to the auto-load value (the content of TIMx\_ARR), then counts from 0 again and generates a count overflow event.

If a repetition counter is used, the update event (UEV) will not be generated until the number of overflows reaches the value of the configured repetition count register plus one (i.e.  $TIMx\_RCR+1$ ); If a repetition counter is not used (i.e.,  $TIMx\_RCR = 0$ ), an update event will be generated every time the count overflows.

Setting the UG bit in the  $TIMx\_EGR$  register (either by software or using a slave mode controller) can also generate an update event.

The UEV event can be disabled by software by setting the UDIS bit in the  $TIMx\_CR1$  register. This is to avoid updating the shadow registers while writing new values in the preload registers. No update event will be generated until the UDIS bit is cleared '0'. Even so, when an update event should occur, the counter is still cleared '0', and the counter inside the prescaler is also cleared '0' (but the value of the prescaler remains unchanged).

Furthermore, if the URS bit in the  $TIMx\_CR1$  register is set (select the update request source), an update event UEV can be generated by setting the UG bit, but the UIF flag bit will not be set (i.e., no interrupt or DMA request will be generated). This is to avoid generating both update and capture interrupts when clearing the counter on the capture event.

When an update event occurs, all of the following registers are updated, and the hardware sets an update flag bit (UIF bit in the  $TIMx\_SR$  register) at the same time (according to the URS bit):

- The repetition counter is reloaded with the content of  $TIMx\_RCR$  register.
- The auto-load shadow register is updated with the preload value ( $TIMx\_ARR$ ).
- The buffer of the prescaler is reloaded with the preload value (content of the  $TIMx\_PSC$  register).

The following figures show some examples of the counter behavior for different clock frequencies when  $TIMx\_ARR=0x36$ .

Figure 23-3 counter timing diagram with internal clock division factor of 1

Figure 23-4 counter timing diagram with internal clock division factor of 2

Figure 23-5 Counter timing diagram, internal clock divided by 4

Figure 23-6 Counter timing diagram, internal clock divided by N

Figure 23-7 Counter timing diagram, update event when ARPE=0 (no TIMx\_ARR preloaded)

Figure 23-8 Counter timing diagram, update event when ARPE=1 (TIMx\_ARR preloaded)

### 23.2.3 Repetition counter

The Time Base Unit explains how an update event (UEV) is generated when the counter overflows, in fact it can only be generated when the repetition counter count reaches 0. This feature is very useful for generating PWM signals.

This means that data is transferred from the preload register to the shadow register (TIMx\_ARR auto-reload register, TIMx\_PSC preload register, and capture/compare register TIMx\_CCRx in comparison mode) only every N+1 count overflow, with N being the value in the TIMx\_RCR repeat count register. The repeat counter is decremented when the counter overflows.

The repetition counter is automatically reloaded and the repetition rate is defined by the value of the TIMx\_RCR register. When the update event is generated by software (by setting the UG bit in

TIMx\_EGR) or by the slave mode controller of hardware, the update event occurs immediately regardless of the value of the repetition counter, and the contents of the TIMx\_RCR register are reloaded to the repetition counter.

Figure 23-9. Examples of update rates in different modes, and register settings for TIMx\_RCR

#### 23.2.4 Clock selection

The counter clock can be provided by the following clock sources:

- Internal clock (CK\_INT)
- External clock mode 1: External input pins (TI1 and TI2)
- Internal Trigger Input (ITRx) (tim15 only): Uses one timer as a prescaler for the other.

##### Internal clock source (CK\_INT)

If the slave mode controller is disabled (SMS = 0000), the CEN and UG bits (TIMx\_EGR register) are de facto control bits and can only be modified by software (the UG bits are still automatically cleared). As long as the CEN bit is written as '1', the clock of the prescaler is provided by the internal clock CK\_INT.

The diagram below shows the operation of the control circuit and up counter in general mode, without the prescaler.

Figure 23-10 Control circuit in normal mode, internal clock divided by 1

**External clock source mode 1**

This mode is selected when SMS=111 in the TIMx\_SMCR register. The counter can count at each rising or falling edge on a selected input.

Figure 23-11 TI2 Example of external clock connection

For example, to configure the counter to count up on the rising edge of the TI2 input, use the following steps:

1. Configure channel 2 to detect rising edges on the TI2 input by writing CC2S = '01' in the TIMx\_CCMR1 register.
2. Configure IC2F [3: 0] of the TIMx\_CCMR1 register and select the input filter bandwidth (if no filter is needed, keep IC2F = 0000);
3. Select rising edge polarity by writing CC2P=0 in the TIMx\_CCER register.
4. Configure the timer in external clock mode 1 by writing SMS=111 in the TIMx\_SMCR register.
5. Select TI2 as the trigger input source by writing TS=00110 in the TIMx\_SMCR register;
6. Enable the counter by writing CEN=1 in the TIMx\_CR1 register.

Note: The capture prescaler is not used for triggering, so it does not need to be configured.

When a rising edge occurs on TI2, the counter counts once and the TIF flag is set.

The delay between the rising edge of TI2 and the actual clock of the counter depends on the synchronization circuit at the input of TI2.

Figure 23-12 Control circuit in external clock mode 1

### 23.2.5 Capture/Compare channels

Each Capture/Compare channel is built around a capture/compare register (including a shadow register), an input stage for capture (with digital filter, multiplexing and prescaler) and an output stage (with comparator and output control).

The next few pictures are an overview of the capture/compare channel.

The input stage samples the corresponding TIx input to generate a filtered signal TIxF. An edge monitor with polarity selection then generates a signal (TIxFPx) that can be triggered as an input from the slave mode controller or as a capture control. It is prescaled before the capture register (ICxPS).

Figure 23-13 Capture/compare channel (example: channel 1 input stage)

The output stage generates an intermediate waveform which is then used for reference: OCxRef (active high). The polarity acts at the end of the chain.

Figure 23-14 Capture/Compare the main circuit of channel 1

Figure 23-15 Output stage of capture/compare channel (channel 1)

The capture/compare block is made of one preload register and one shadow register. Write and read always access the preload register.

In capture mode, captures are actually done in the shadow register, which is copied into the preload register.

In compare mode, the content of the preload register is copied into the shadow register which is compared to the counter.

### 23.2.6 Input capture mode:

In input capture mode, when the corresponding edge on the ICx signal is detected, the current value of the counter is latched into the capture/compare register (TIMx\_CCRx). When a capture event occurs, the corresponding CCxIF flag (TIMx\_SR register) is set to 1, and if an interrupt or DMA operation is enabled, an interrupt or DMA request will be generated. If the CCxIF flag is already high when the capture event occurs, the over-capture flag CCxOF (TIMx\_SR register) is set to 1. The CCxIF can be cleared by writing CCxIF = 0, or by reading the captured data stored in the TIMx\_CCRx register. CCxOF is cleared when you write it to '0'.

The following example shows how to capture the counter value in TIMx\_CCR1 when TI1input rises. To do this, use the following procedure:

- Select valid input: TIMx\_CCMR1 must be connected to the TI1 input, so CC1S = 01 written in the TIMx\_CCMR1 register, as long as CC1S is not '00', the channel is configured as input, and the TIMx\_CCR1 register becomes read-only.
- Program the input filter duration you need with respect to the signal you connect to the timer (when the input is one of the TIx (ICxF bits in the TIMx\_CCMRx register)). Let's imagine that, when toggling, the input signal is not stable during at most 5 internal clock cycles. We must program a filter duration longer than these 5 clock cycles. We can validate a transition on TI1 when 8 consecutive samples with the new level have been detected (sampled at fDTS frequency). Then write IC1F bits to 0011 in the TIMx\_CCMR1 register.
- Select the valid transition edge of the TI1 channel and write CC1P = 0 (set to rising edge) in the TIMx\_CCER register.
- Program the input prescaler. In our example, we wish the capture to be performed at each valid transition, so the prescaler is disabled (write IC1PS bits to '00' in the TIMx\_CCMR1 register).
- Enable capture from the counter into the capture register by setting the CC1E bit in the TIMx\_CCER register.
- If desired, the associated interrupt request may be allowed by setting the CC1IE bit in the TIMx\_DIER register, or the DMA request may be allowed by setting the CC1DE bit in the TIMx\_DIER register.

When an input capture occurs:

- The TIMx\_CCR1 register gets the value of the counter on the active transition.
- The CC1IF flag bit is set (interrupt flag). CC1OF is also set if at least two consecutive captures occurred whereas the flag was not cleared.
- An interrupt is generated depending on the CC1IE bit.
- A DMA request is generated depending on the CC1DE bit.

In order to handle the overcapture, it is recommended to read the data before the overcapture flag. This is to avoid missing an overcapture which could happen after reading the flag and before reading the data.

Note: IC interrupt and/or DMA requests can be generated by software by setting the corresponding CCxG bit in the TIMx\_EGR register.

### 23.2.7 PWM input mode (only for tim15)

This mode is a special case of the input capture mode, and the rest of the operation is the same as the input capture mode except for the following differences:

- Both ICx signals are mapped to the same TIx input.
- These 2 ICx signals are active on edges with opposite polarity.
- One of the two TIxFP signals is selected as trigger input and the slave mode controller is configured in reset mode.

For example, the user can measure the cycle (TIMx\_CCR1 register) and the duty cycle (TIMx\_CCR2 register) of the PWM signal input to TI1 as follows

- Select the active input for TIMx\_CCR1: write the CC1S bits to 01 in the TIMx\_CCMR1 register (TI1 selected).
- Select the active polarity for TI1FP1 (used both for capture in TIMx\_CCR1 and counter clear): write the CC1P bit to '0' (active on rising edge).
- Select the active input for TIMx\_CCR2: write the CC2S bits to 10 in the TIMx\_CCMR1 register (TI1 selected).
- Select the active polarity for TI1FP2 (used for capture in TIMx\_CCR2): write the CC2Pbit to '1' (active on falling edge).
- Select the valid trigger input: write the TS bits to 101 in the TIMx\_SMCR register (TI1FP1 selected).
- Configure the slave mode controller in reset mode: write the SMS bits to 100 in the TIMx\_SMCR register.
- Enable the captures: write the CC1E and CC2E bits to '1' in the TIMx\_CCER register.

Figure 23-16 PWM input mode timing

Because only TI1FP1 and TI2FP2 are connected to the slave mode controller, the PWM input mode can only use the TIMx\_CH1/TIMx\_CH2 signal.

### 23.2.8 Forced output mode

In output mode (CCxS bits = 00 in the TIMx\_CCMRx register), each output compares signal(OCxREF and then OCx/OCxN) can be forced to active or inactive level directly by software, independently of any comparison between the output compare register and the counter.

Set the corresponding OCxM = 0101 in the TIMx\_CCMRx register to force the output comparison signal (OCxREF/OCx) to an active state. Thus OCxREF is forced high (OCxREF is always active high) and OCx get opposite value to CCxP polarity bit.

For example: CCxP=0 (OCx active high) => OCx is forced to high level.

The OCxREF signal can be forced low by writing the OCxM bits to 0100 in the TIMx\_CCMRx register. Anyway, the comparison between the TIMx\_CCRx shadow register and the counter is still performed and allows the flag to be set. Interrupt and DMA requests can be sent accordingly. This is described in the output compare mode section below.

### 23.2.9 Output compare mode

This function is used to control an output waveform or indicate that a given period of time has expired.

When a match is found between the capture/compare register and the counter, the output compare function:

- Assigns the corresponding output pin to a programmable value defined by the output compare mode (OCxM bits in the TIMx\_CCMRx register) and the output polarity (CCxP bit in the TIMx\_CCER register). The output pin can keep its level (OCxM=0000), be set active (OCxM=0001), be set inactive (OCxM=0010) or can toggle (OCxM=0011) on match.
- Sets a flag in the interrupt status register (CCxIF bit in the TIMx\_SR register).
- Generates an interrupt if the corresponding interrupt mask is set (CCXIE bit in the TIMx\_DIER register).
- If the corresponding enable bit is set (CCxDE bit in the TIMx\_DIER register, CCDS bit in the TIMx\_CR2 register selects the DMA request function), a DMA request is generated.

You can select whether the TIMx\_CCRx register needs to use a preload register by configuring the OCxPE bit in TIMx\_CCMRx.

In output compare mode, the update event UEV has no effect on OCxREF and OCx output. The timing resolution is one count of the counter. Output compare mode can also be used to output a single pulse (in One Pulse mode).

Procedure:

1. Select the counter clock (internal, external, prescaler).
2. Write the desired data in the TIMx\_ARR and TIMx\_CCRx registers.
3. Set the CCxIE bit if an interrupt request is to be generated.
4. Select the output mode. For example:
  - Write OCxM = 0011 to toggle OCx output pin when CNT matches CCRx
  - Write OCxPE = 0 to disable preload register
  - Write CCxP = 0 to select active high polarity
  - Write CCxE = 1 to enable the output
5. Enable the counter by setting the CEN bit in the TIMx\_CR1 register.

The TIMx\_CCRx register can be updated by software at any time to control the output waveform, provided the preload register is not used (OCxPE = '0', otherwise the shadow register of TIMx\_CCRx can only be updated when the next update event occurs). An example is given in the figure below.

Figure 23-17 Output comparison mode, flip OC1

### 23.2.10 PWM mode

The pulse width modulation mode may produce a signal whose frequency is determined by the TIMx\_ARR register and whose duty cycle is determined by the TIMx\_CCRx register.

The OCxM bit in the TIMx\_CCMRx register is written to '0110' (PWM mode 1) or '0111' (PWM mode 2), and each OCx output channel can be independently set to generate a PWM. The corresponding preload register must be enabled by setting the OCxPE bit of the TIMx\_CCMRx register, and finally setting the ARPE bit of the TIMx\_CR1 register to enable the preload register that can be automatically reloaded.

The preload register can only be transferred to the shadow register when an update event occurs, so the user must initialize all registers by setting the UG bit in the TIMx\_EGR register before the counter starts counting.

OCx polarity is software programmable using the CCxP bit in the TIMx\_CCER register. It can be programmed as active high or active low. OCx output is enabled by a combination of the CCxE, CCxNE, MOE, OSSI and OSSR bits (TIMx\_CCER and TIMx\_BDTR registers). Refer to the TIMx\_CCER register description for more details.

In PWM mode (1 or 2), TIMx\_CNT and TIMx\_CCRx are always compared to determine whether  $TIMx\_CCRx \leq TIMx\_CNT$  or  $TIMx\_CNT \leq TIMx\_CCRx$  (depending on the direction of the counter).

Figure 23-18 Edge-aligned PWM waveforms (ARR=8)

#### Jitter mode

The DITHEN bit of the TIMx\_CR1 register may be enabled to turn on the jitter mode to improve the effective resolution of the PWM mode. Can be applied to CCR (improved duty cycle resolution) and ARR (improved resolution of PWM frequency)

The principle of operation is to make the actual CCR (or ARR) value change slightly (with or without increasing a timer cycle) over 16 consecutive PWM cycles, and how the change can be set by predefined settings. When calculating the average duty cycle, you can achieve a 16-fold increase in resolution. The figure below shows the jitter principle of four consecutive PWM periods

Figure 23-19 jitter principle

When jitter mode is enabled, the value of the register will automatically change as follows:

- The lowest 4 bits is the encoding for improving resolution (fractional part)
- The high bit is shifted left to 19: 4 for encoding as the base value (integer part)

Note: When dither mode is on or off, the values of ARR and CCR are automatically updated (for example,  $ARR = 0x05$  when  $DITHEN = 0$ , then  $ARR = 0x50$  when  $DITHEN = 1$ ), the following steps must be followed when resetting the DITHEN bit

1. CEN and ARPE bits must be reset
2. The ARR [3: 0] bit must be reset
3. The DITHEN bit must be reset
4. The CCIF flag must be cleared
5. CEN bit can be set (ARPE = 1 can be set)

Figure 23-20 Data mapping and register coding in dither mode

The minimum frequency is calculated as follows:

$$\text{According to resolution} = \frac{\text{定时器频率}}{\text{PWM 频率}} \quad \text{push out: minimum PWM frequency} = \frac{\text{定时器频率}}{\text{最大分辨率}}$$

$$\text{In jitter-free mode: Minimum PWM frequency} = \frac{\text{定时器频率}}{65536}$$

$$\text{When there is jitter mode: minimum PWM frequency} = \frac{\text{定时器频率}}{65535 + \frac{15}{16}}$$

Note: The maximum values of TIMx\_arr and TIMxCCRy in jitter mode are limited to 0xFFFFEF (corresponding to 65534 in the integer part and 15 in the jitter part). Exceeding 0xFFFFEF, there will be an overflow situation, that is, arr = 0xFFFF+1 = 0.

The figure below shows that in jitter mode, the resolution of the PWM can be improved regardless of the PWM frequency

Figure 23-21 PWM Resolution VS Frequency

The duty cycle and cycle changes in 16 consecutive cycles are as follows:

Figure 23-22 PWM Jitter Mode

The auto-reload and compare value increments are distributed in a specific pattern as described in the following table, with the incremental distribution of the jitter sequence as uniformly as possible, minimizing the overall ripple

Table 23-1 CCR and ARR Register Jitter Changes

| LSB value | PWM Cycle |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |
|-----------|-----------|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|
|           | 1         | 2  | 3  | 4  | 5  | 6  | 7  | 8  | 9  | 10 | 11 | 12 | 13 | 14 | 15 | 16 |
| 0000      |           |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |
| 0001      | +1        |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |
| 0010      | +1        |    |    |    |    |    |    |    | +1 |    |    |    |    |    |    |    |
| 0011      | +1        |    |    |    | +1 |    |    |    | +1 |    |    |    |    |    |    |    |
| 0100      | +1        |    |    |    | +1 |    |    |    | +1 |    |    |    | +1 |    |    |    |
| 0101      | +1        |    | +1 |    | +1 |    |    |    | +1 |    |    |    | +1 |    |    |    |
| 0110      | +1        |    | +1 |    | +1 |    |    |    | +1 |    | +1 |    | +1 |    |    |    |
| 0111      | +1        |    | +1 |    | +1 |    | +1 |    | +1 |    | +1 |    | +1 |    |    |    |
| 1000      | +1        |    | +1 |    | +1 |    | +1 |    | +1 |    | +1 |    | +1 |    | +1 |    |
| 1001      | +1        | +1 | +1 |    | +1 |    | +1 |    | +1 |    | +1 |    | +1 |    | +1 |    |
| 1010      | +1        | +1 | +1 |    | +1 |    | +1 |    | +1 | +1 | +1 |    | +1 |    | +1 |    |
| 1011      | +1        | +1 | +1 |    | +1 | +1 | +1 |    | +1 | +1 | +1 |    | +1 |    | +1 |    |

### 23.2.11 Combined PWM mode (tim15 only)

The combined PWM mode allows the PWM signal to be generated by programmable delay and phase shift between pulses. The frequency is determined by the ARR and the duty cycle and delay are determined by the two CCRs. The resulting signal ocxrefc is generated by AND/OR logic between two reference PWMs

- The OC1REFC(orOC2REFC) is controlled by TIMx\_CCR1 and TIMx\_CCR2

Asymmetric PWM modes can be independently selected on dual channels (each pair of CCR registers controls one OCx output) by writing to OCxM 1100 (combined PWM mode 1, logic OR output) and OCxM 1101 (combined PWM mode 2, logic AND output)

When a given channel is used as a combined PWM channel, its complementary channels must be configured in opposite PWM modes (e.g., one for combined PWM mode 1 and one for combined PWM mode 2).

The following figure shows an example of a combined mode generation signal, including

- Channel 1 is combined PWM mode 2
- Channel 2 is PWM Mode 1

Figure 23-23 Combined PWM patterns for channel 1 and channel 2

### 23.2.12 Complementary outputs and dead-time insertion

The universal control timer (TIM15\_16\_17) can output two complementary signals and can manage the instantaneous turn-off and turn-on of the output.

This time is generally known as dead-time, and you have to adjust it depending on the devices you have connected to the outputs and their characteristics (intrinsic delays of level-shifters, delays due to power switches...)

You can select the polarity of the outputs (main output OCx or complementary OCxN) independently for each output. This is done by writing to the CCxP and CCxNP bits in the TIMx\_CCER register.

The complementary signals OCx and OCxN are controlled by a combination of the following control bits: the CCxE and CCxNE bits of the TIMx\_CCER register, the MOE, OISx, OISxN, OSSI and OSSR bits of the TIMx\_BDTR and TIMx\_CR2 registers, as detailed in the control bits of the complementary output channels OCx and OCxN with brake function. In particular, the dead-time is activated when switching to the IDLE state (MOE falling down to 0).

Dead-time insertion is enabled by setting both CCxE and CCxNE bits, and the MOE bit if the break circuit is present. By configuring the DTG [7: 0] bit in the TIMx\_BDTR register, you can control the dead time generator for all channels. From a reference waveform OCxREF, it generates 2 outputs OCx and OCxN. If OCx and OCxN are active high:

- The OCx output signal is the same as the reference signal except for the rising edge, which is delayed relative to the reference rising edge.
- The OCxN output signal is the opposite of the reference signal except for the rising edge, which is delayed relative to the reference falling edge.

If the delay is greater than the width of the active output (OCx or OCxN) then the corresponding pulse is not generated.

The following figures show the relationships between the output signals of the dead-time generator and the reference signal OCxREF. (we suppose CCxP=0, CCxNP=0, MOE=1, CCxE=1 and CCxNE=1 in these examples)

Figure 23-24 Complementary output with dead-time insertion

Figure 23-25 Dead-time waveforms with delay greater than the negative pulse

Figure 23-26 Dead-time waveforms with delay greater than the positive pulse.

When DTAE = 1, the rising edge dead time is configured by the DTG [7: 0] bit of TIMx\_BDTR, and the falling edge dead time is configured by the DTGF [7: 0] bit of TIMx\_DTR2. The writing of the DTAE needs to be before the counter is enabled. When CEN = 1, it is not allowed to modify the DTAE.

The dead time can be modified during the PWM operation through the mechanism of preloading. When the DTPE of TIMX\_DTR2 is set, the dead time configuration registers DTG [7: 0] and DTGF [7: 0] are preloaded, and the preloaded data is loaded into the cache register at the next update event.

Note: If the DTPE bit is set while the counter is enabled, new data written since the last update is discarded and the previous value is used

Figure 23-27 asymmetric dead time

### 23.2.12.1 Re-directing OCxREF to OCx or OCxN

In output mode (forced, output compare or PWM), OCxREF can be re-directed to the OCx output or to OCxN output by configuring the CCxE and CCxNE bits in the TIMx\_CCER register.

This allows you to send a specific waveform (such as PWM or static active level) on one output while the complementary remains at its inactive level. Other alternative possibilities are to have both outputs at inactive level or both outputs active and complementary with dead-time.

Note: When only OCxN is enabled ( $CCxE = 0$ ,  $CCxNE = 1$ ), it does not invert and becomes high immediately when OCxREF is active. For example, if  $CCxNP=0$  then  $OCxN=OCxREF$ . On the other hand, when both OCx and OCxN are enabled ( $CCxE=CCxNE=1$ ) OCx becomes active when OCxREF is high whereas OCxN is complemented and becomes active when OCxREF is low.

### 23.2.13 Using the break function

The purpose of the brake function is to protect the power switch driven by the PWM output from the TIMER. The input to the two-way brakes is usually the fault output connected to the three-phase inverter and power stage chip. When the brake signal is active, it will immediately turn off all outputs of the PWM and force them to a preset safe level state. Some internal events of the MCU can also be used as trigger signals to turn off the output.

There are two channels of braking events. Channel 1 includes system-level faults (clock failure, ECC, parity, etc.) and application-level faults (through input pins or built-in comparators), and can be forced to output to a preset level (whether working or idle) after a dead zone. Channel 2 contains only some application layer faults and forces the output to an invalid state.

The output enable signal and output level during braking are controlled by the following bits

- The MOE bit of TIMx\_BDTR can be enabled and turned off by software or 2-way brake event reset
- The OSSI bit of TIMx\_BDTR is used to define whether the timer also controls the output when idle, or releases control of the GPIO controller (high impedance state)
- The OISx and OISxN bits of TIMx\_CR2 are used to set the output to an invalid level regardless of the working or idle state, and the OCx and OCxN outputs cannot be set to an active level at the same time at the same time, regardless of the values of OISx and OISxN.

When exiting from reset, the brake function is turned off and the MOE is 0. The brake function can be turned on by enabling the BKE bit of TIMxBDTR. The polarity of the brake inputs can be configured via BKP. BKEx and BKPx can be modified simultaneously. When the BKE and BKP bits are written, a delay of 1 APB clock cycle is applied before the writing is effective. Consequently, it is necessary to wait 1 APB clock period to correctly read back the bit after the write operation.

MOE falling edge can be asynchronous, thus a resynchronization circuit has been inserted between the actual signal (acting on the outputs) and the synchronous control bit (accessed in the TIMx\_BDTR register). It results in some delays between the asynchronous and the synchronous signals. In particular, if you write MOE to 1 whereas it was low, you must insert a delay (dummy instruction) before reading it correctly. This is because the write acts on the asynchronous signal whereas the read reflects the synchronous signal.

A source of the brake channel;

- An external source can be connected to one of the TIMx\_BKIN pins (select GPIO and configuration registers), plus polarity selection and filtering
- The internal source contains 2 parts

- Signal from brake comparator (tim\_brk\_cmpx)
- From system brake request

The brake event can also be generated by software, and the BG bit of TIMx\_EGR can be set, with all brake sources OR up as the tim\_brk brake input. Figure below:

Figure 23-28 Brake circuit

Note: Asynchronous operation can only be guaranteed when there is no filtering. If filtering is turned on, a failsafe clock mode must be used to ensure that brake interrupt events are handled (e.g. using internal PLL or CSS, no filtering).

When a break occurs (selected level on the break input):

- The MOE bit is cleared asynchronously, placing the output in an invalid state, an idle state, or releasing control of the GPIO controller (selected by the OSS1 bit). This feature functions even if the MCU oscillator is off.
- Each output channel is driven with the level programmed in the OISx bit in the TIMx\_CR2 register as soon as MOE=0. If OSS1 = 0, the timer releases output control, otherwise the enable output is always high.
- When complementary outputs are used:
  - The output is first put into a reset state, i.e. an invalid state (depending on polarity). This is done asynchronously so that it works even if no clock is provided to the timer.
  - If the clock of the timer still exists, the dead time generator will re-take effect, driving the output port according to the level indicated by the OISx and OISxN bits after the dead time. Even in this case, OCx and OCxN cannot be driven to their active level together. Note that the dead time is longer than usual (approximately 2 clock cycles) because of the resynchronization of the MOE.
  - if OSS1 = 0, the timer releases the output, otherwise keeps the output enabled; Or once one of CCxE and CCxNE becomes high, the enable output becomes high.
- The brake status flag is pulled up (BIF of TIMx\_SR). If the BIE bit in the TIMx\_DIER register is set, an interrupt is generated when the brake status flag (BIF bit in the TIMx\_SR register) is '1'.

If the TDE bit in the TIMx\_DIER register is set, a DMA request is generated.

- If the AOE bit in the TIMx\_BDTR register is set, the MOE bit is automatically set again at the next update event UEV. This can be used to perform a regulation, for instance. Otherwise, the MOE remains low until it is set to '1' again; At this time, this feature can be used in safety. You can connect the brake input to the power-driven alarm output, thermal sensor or other safety devices.

Note: When AOE is 1, if MOE is reset by the CPU, the output will enter the idle state and be forced to an invalid level or high impedance (depending on the value of OSS1). If both MOE and AOE are reset by the CPU, the output will enter the invalid state and the output level is driven by the OISx bit.

Note: The break inputs are active on level. Thus, the MOE cannot be set while the break input is active (neither automatically nor by software). In the meantime, the status flag BIF can not be cleared.

In addition to the break input and the output management, a write protection has been implemented inside the break circuit to safeguard the application. It allows the user to freeze several configuration parameters (dead time duration, OCx/OCxN polarity and disabled state, OCxM configuration, brake enable and polarity). The user can select one of the three levels of protection by setting the LOCK bit in the TIMx\_BDTR register, see Brake and Dead Time Register (TIMx\_BDTR). The LOCK bits can be written only once after an MCU reset.

The figure below shows an example of behavior of the outputs in response to a break.

Figure 23-29 Output behavior in response to a break

### 23.2.14 Bidirectional brake input

TIM15/16/17 has two-way brake I/O, as shown in the figure below:

Figure 23-30 Output Redirection

I/O support features:

- Provides a board-level global brake signal that sends a fault signal to the external MCU and gate driver through a unique pin that can be used as both input and output
- When it is necessary to combine a plurality of internal and external brake sources, the internal brake source and the plurality of external open-drain sources are OR calculated as the unique trigger signal of the braking event

The input of `tim_brk` is controlled to be bidirectional by the `BKBID` bit of `TIMxBDTR`. The `BKBID` can be set to 1 using the `LOCK` bit (`LOCK` level 1) of `TIMxBDTR`, and the implementation is locked into read-only mode.

The `tim_brk` input may use bidirectional mode and requires I/O to be configured in open-drain mode with low active polarity (via `BKINP`, `BKP` control bits). Whether from the system (e.g. CCS), from the board-level peripheral, or the brake input forcing a low level indicates a brake input failure event, it can be used as a brake request. However, for safety reasons, when the polarity bit is not effectively configured (when configured to be active high), the bidirectional mode is disabled.

The software braking event (BG) will also cause the brake I/O to be pulled down, which is used to show external devices that this timer has entered the braking state. Of course, it can only be possible when `BKE` is 1. When `BKE` is 0, a software brake event occurs, the output is set to a safe state and a brake flag signal is generated, but it has no effect on `TIMx_BKIN` I/O.

A safe release mechanism prevents the system from being restrictively locked (a low level at the brake input triggers a brake, which in turn forces the input to low level).

When the `BKDSRM` bit is set to 1, the brake output control can be released, clearing the fault flag signal and providing the possibility to reconfigure the system.

Under no circumstances should the brake protection circuit be turned off:

- The brake input path is always active: even if the BKDSRM bit is set to 1 and the open-drain control is released, the brake event is still active. This prevents that PWM output from being re-started while still in the brake state
- When the output is enabled (MOE = 1), the BKDSRM bit cannot release brake protection

Table 23-2 Brake protection status

| MOE | BKBID | BKDSRM | Brake protection status |
|-----|-------|--------|-------------------------|
| 0   | 0     | X      | Enable                  |
| 0   | 1     | 0      | Enable                  |
| 0   | 1     | 1      | 1 1 Disarmed            |
| 1   | X     | X      | Enable                  |

#### 23.2.14.1 Enable and re-enable the brake circuit

By default, the brake circuit (in input or bi-directional mode) is enabled

Follow the following procedure to restart the protection after braking occurs:

- The BKDSRM bit must be set to 1 to release output control
- The software must wait until the system brake status disappears and then clear the SBIF status flag (or systematically clear it before re-enabling)
- The software must poll the BKDSRM bit until it is cleared by the hardware (when the application brake state disappears)

In this way, the brake circuit is activated and the MOE bit can be re-enabled for the PWM output

#### 23.2.15 Clearing the OCxREF signal on an external event

For a given channel, setting the corresponding OCxCE bit in the TIMx\_CCMRx register to '1' enables the OCxREF signal to be pulled low with a high level at the OCREF\_CLR\_INT input, and the OCxREF signal will remain low until the update event UEV generated by the next count overflow occurs. This function can only be used in output compare and PWM modes. It does not work in Forced mode. The OCREF\_CLR\_INT input can be selected among several inputs as shown in the figure below.

Figure 23-31 OCREF\_CLR input selection

### 23.2.16 Generate a six-step PWM output

When complementary outputs are used on a channel, preload bits are available on the OCxM, CCxE and CCxNE bits. These preload bits are transferred to the shadow register when a COM commutation event occurs. In this way, you can pre-set the configuration of the next step and change the configuration of all channels at the same time. COM can be generated by software by setting the COMG bit in the TIMx\_EGR register or by hardware (on TRGI rising edge).

When a COM event occurs, a flag bit (COMIF bit in the TIMx\_SR register) will be set. At this time, if the COMIE bit of the TIMx\_DIER register has been set, an interrupt will be generated; If the COMDE bit of the TIMx\_DIER register has been set, a DMA request is generated.

The figure below describes the behavior of the OCx and OCxN outputs when a COM event occurs, in 3 different examples of programmed configurations.

Figure 23-32 generates a six-step PWM, using COM example (OSSR = 1)

### 23.2.17 One-pulse mode

One-pulse mode (OPM) is a particular case of the previous modes. It allows the counter to be started in response to a stimulus and to generate a pulse with a programmable length after a programmable delay.

Starting the counter can be controlled through the slave mode controller. Generating the waveform can be done in output compare mode or PWM mode. One-pulse mode is selected by setting the OPM bit in the TIMx\_CR1 register. This makes the counter stop automatically at the next update event UEV. A pulse can be correctly generated only if the compare value is different from the counter initial value. Before starting (when the timer is waiting for the trigger), the configuration must be:

- Up count mode: counter  $CNT < CCRx \leq ARR$  (in particular,  $0 < CCRx$ ),
- Down counting mode: Counter  $CNT > CCRx$ .

Figure 23-33 Example of one pulse mode

For example one may want to generate a positive pulse on OC1 with a length of  $t_{PULSE}$  and after a delay of  $t_{DELAY}$  as soon as a positive edge is detected on the TI2 input pin.

Assume TI2FP2 as the trigger:

- Map TI2FP2 on TI2 by writing  $CC2S=01$  in the  $TIMx\_CCMR1$  register.
- TI2FP2 must detect a rising edge, write  $CC2P=0$  in the  $TIMx\_CCER$  register.
- Configure TI2FP2 as trigger for the slave mode controller (TRGI) by writing  $TS=110$  in the  $TIMx\_SMCR$  register.
- TI2FP2 is used to start the counter by writing  $SMS$  to '110' in the  $TIMx\_SMCR$  register (trigger mode).

The OPM waveform is defined by writing the compare registers (taking into account the clock frequency and the counter prescaler).

- The  $t_{DELAY}$  is defined by the value written in the  $TIMx\_CCR1$  register.
- The  $t_{PULSE}$  is defined by the difference between the auto-reload value and the compare value ( $TIMx\_ARR - TIMx\_CCR1$ ).
- Let's say one want to build a waveform with a transition from '0' to '1' when a compare match occurs and a transition from '0' to '1' when the counter reaches the auto-reload value. To do this PWM mode 2 must be enabled by writing  $OC1M=111$  in the  $TIMx\_CCMR1$  register. Optionally the preload registers can be enabled by writing  $OC1PE=1$  in the  $TIMx\_CCMR1$  register and  $ARPE$  in the  $TIMx\_CR1$  register. In this case one has to write the compare value in the  $TIMx\_CCR1$  register, the auto-reload value in the  $TIMx\_ARR$  register, generate an update by setting the  $UG$  bit and wait for external trigger event on TI2.  $CC1P$  is written to '0' in this example.

Since only 1 pulse (Single mode) is needed, a 1 must be written in the  $OPM$  bit in the  $TIMx\_CR1$  register to stop the counter at the next update event (when the counter rolls over from the auto-reload value back to 0) When  $OPM$  bit in the  $TIMx\_CR1$  register is set to '0', so the repetitive mode is selected.

#### 23.2.17.1 Particular case: OCx fast enable:

In One-pulse mode, the edge detection on  $TIx$  input set the  $CEN$  bit which enables the counter. Then the comparison between the counter and the compare value makes the output toggle. But several clock cycles are needed for these operations, and it limits the minimum delay  $t_{DELAY}$  min we can get.

If one wants to output a waveform with the minimum delay, the OCxFE bit can be set in the TIMx\_CCMRx register. Then OCxREF (and OCx) is forced in response to the stimulus, without taking in account the comparison. Its new level is the same as if a compare match had occurred. OCxFE acts only if the channel is configured in PWM1 or PWM2mode.

### 23.2.18 Retriggerable single pulse mode (tim15 only)

This mode allows the counter to start in response to excitation and generate pulses of programmable length, which differs from the non-retriggerable single pulse mode described in the previous section as follows:

- The pulse starts as soon as the trigger occurs (no programmable delay).
- If a new trigger occurs before the pulse generated by the previous trigger is completed, the pulse is extended.

To use the retriggerable monopulse mode, the timer must be in slave mode, the bit SMS [3: 0] = "1000" in the TIMx\_SMCR register (combined mode-reset + trigger), and the OCxM [3: 0] bit set to "1000" or "1001" (retriggerable OPM mode 1 or 2).

Note: For compatibility reasons, the OCxM [3: 0] and SMS [3: 0] bit fields are split into two parts, with the most significant bit not contiguous with the 3 least significant bit positions.

Figure 23-34 Example of a retriggerable monopulse mode

### 23.2.19 UIF bit remapping

The UIFREMAP bit of the TIMx\_CR1 register can force a continuous copy of the UIF to the 31st bit of the timer counter (TIMxCNT [31]). This allows both the value of the counter and a potential rolling state exhibited by the UIFCPY flag signal to be read out. In special cases, this can simplify the calculation by avoiding race conditions, for example by simultaneous processing of counter readout and update interrupts.

The UIF and UIFCPY flags are generated without delay.

### 23.2.20 Timer input XOR function (tim15 only)

The TI1S bit in the TIMx\_CR2 register allows the input filter of channel 1 to be connected to the output of an exclusive OR gate. The two inputs of the exclusive OR gate are TIMx\_CH1 and TIMx\_CH2.

The XOR output can be used with all the timer input functions such as trigger or input capture. It is useful for measuring the spacing between the edges of two input signals.

### 23.2.21 Synchronization of TIMx timer and externally triggered

The TIMx timer can be synchronized with an external trigger in multiple modes: reset mode, gated mode, trigger, reset + trigger and gated + reset mode.

### 23.2.21.1 Slave mode: Reset mode

When a trigger input event occurs, the counter and its prescaler can be re-initialized; Meanwhile, if the UDIS bit of the TIMx\_CR1 register is low, an update event UEV is also generated; All preload registers (TIMx\_ARR, TIMx\_CCRx) are then updated.

In the following example, the upcounter is cleared in response to a rising edge on TI1 input:

- Configure the channel 1 to detect rising edges on TI1. Configure the input filter duration (in this example, we do not need any filter, so we keep IC1F=0000). The capture prescaler is not used for triggering, so it does not need to be configured. The CC1S bits select the input capture source only, CC1S=01 in TIMx\_CCMR1 register. Write CC1P=0 in TIMx\_CCER register to validate the polarity (and detect rising edges only).
- Configure the timer in reset mode by writing SMS=0100 in TIMx\_SMCR register. Select TI1 as the input source by writing TS=00101 in TIMx\_SMCR register.
- Enable the counter by writing CEN=1 in the TIMx\_CR1 register.

The counter starts counting on the internal clock, then behaves normally until TI1 rising edge. When TI1 rises, the counter is cleared and restarts from 0. At the same time, a trigger flag (TIF bit in the TIMx\_SR register) is set, and an interrupt request or a DMA request is generated according to the setting of the TIE (Interrupt Enable) bit and the TDE (DMA Enable) bit in the TIMx\_DIER register.

The following figure shows this behavior when the auto-reload register TIMx\_ARR=0x36. The delay between the rising edge on TI1 and the actual reset of the counter is due to the resynchronization circuit on TI1 input.

Figure 23-35 Control circuit in reset mode

### 23.2.21.2 Slave mode: Gated mode

The counter can be enabled depending on the level of a selected input.

In the following example, the upcounter counts only when TI1 input is low:

- Configure the channel 1 to detect low levels on TI1. Configure the input filter duration (in this example, we do not need any filter, so we keep IC1F=0000). The capture prescaler is not used for triggering, so it does not need to be configured. The CC1S bits select the input capture source only, CC1S=01 in TIMx\_CCMR1 register. Write CC1P=1 in TIMx\_CCER register to validate the polarity (and detect low level only).
- Configure the timer in gated mode by writing SMS=101 in TIMx\_SMCR register. Select TI1 as the input source by writing TS=101 in TIMx\_SMCR register.
- Enable the counter by writing CEN=1 in the TIMx\_CR1 register. In gated mode, the counter

doesn't start if CEN=0, whatever is the trigger input level.

The counter starts counting on the internal clock as long as TI1 is low and stops as soon as TI1 becomes high. The TIF flag in the TIMx\_SR register is set both when the counter starts or stops.

The delay between the rising edge on TI1 and the actual stop of the counter is due to the resynchronization circuit on TI1 input.

Figure 23-36 Control circuit in Gated mode

### 23.2.21.3 Slave mode: Trigger mode

The selected event on the input enables the counter.

In the following example, the upcounter starts in response to a rising edge on TI2 input:

- Configure the channel 2 to detect rising edges on TI2. Configure the input filter duration (in this example, we do not need any filter, so we keep IC2F=0000). The capture prescaler is not used for triggering, so it does not need to be configured. The CC2S bits are configured to select the input capture source only, CC2S=01 in TIMx\_CCMR1 register. Write CC2P=1 in TIMx\_CCER register to validate the polarity (and detect low level only).
- Configure the timer in trigger mode by writing SMS=110 in TIMx\_SMCR register. Select TI2 as the input source by writing TS=110 in TIMx\_SMCR register.

When a rising edge occurs on TI2, the counter starts counting on the internal clock and the TIF flag is set.

The delay between the rising edge on TI2 and the actual start of the counter is due to the resynchronization circuit on TI2 input.

Figure 23-37 Control circuit in trigger mode

**23.2.21.4 Slave mode: reset plus trigger combination mode (tim15 only)**

In this mode, the rising edge of the trigger input initializes the counter and generates an update signal for the register, turning on the counting

This mode is used for a single pulse mode

**23.2.21.5 Slave mode: gated plus reset combination mode (tim15 only)**

The clock of the counter is enabled only when the trigger input is high. The counter stops when the trigger signal is pulled low. The start and stop of the counter can be controlled

This mode allows detection of out-of-range PWM signals (duty cycle exceeding maximum expected value)

**23.2.22 Timer synchronization (tim15)**

The TIMx timers are linked together internally for timer synchronization or chaining. See Section 20.2.22: Timer Synchronization for details.

**23.2.23 DMA Burst Mode**

The TIMx timer has the ability to generate multiple DMA requests when a single event occurs. The main purpose is to be able to reprogram some functions of the timer multiple times without the overhead of software. But it is also possible to read several registers in a row at fixed intervals.

The destination of the DMA controller is unique and must point to the virtual register TIMx\_DMAR. When a given timer event occurs, the timer initiates a series of DMA requests. Each write to the TIMx\_DMAR register actually redirects a timer register.

The DBL [4: 0] bit in the TIMx\_DCR register sets the DMA burst length. When a read or write access is made to a TIMx\_DMR address, the timer recognizes burst transmissions, that is, the number of transmissions (in half a word or byte)

The DBA [4: 0] bit of TIMx\_DCR defines the DMA base address for DMA transmission (when read and write operations are completed through the TIMx\_DMAR address). The DBA is defined as the offset from the TIMx\_CR1 register address.

Example:

00000: TIMx\_CR1

00001: TIMx\_CR2

00010: TIMx\_SMCR

As an example, the timer DMA burst characteristic is used to update the contents in the CCRx register when an update event occurs, transmitting a half-word to CCRx by DMA.

This is done through the following steps:

1. Configure the corresponding DMA channel as follows:
  - a) The DMA channel peripheral address is the address of the DMAR register
  - b) The DMA channel storage address is the BUFF address in RAM, which contains the data transmitted by DMA to CCRx
  - c) Number of data transferred = 3 (see note)
  - d) Polling Mode Off
2. Configure DCR registers by configuring DBA and DBL: DBL = 3, DBA = 0XE
3. Enable timer update DMA request (UDE = 1)

4. Enable timer
5. Enable the DMA channel

This example applies to the case where each CCRx register is updated once. If each CCRx is updated twice, the number of data transfers needs to be set to 4. For example, suppose that the buffer of RAM contains data1, data2, data3, and data4. Data is sequentially transmitted to CCRx: the first update DMA request, data1 is transmitted to CCR1, and data2 is transmitted to CCR2; For the second update of the DMA request, data3 is transmitted to CCR1 and data4 is transmitted to CCR2.

Note: Null values can be written to the reserved register

### 23.2.24 DMA Request

TIM15/TIM16/TIM17 can generate DMA requests as shown in the following table:

Table 23-3 DMA Request

| DMA request source | DMA enable control bit |
|--------------------|------------------------|
| update             | UDE                    |
| Compare/Capture 1  | CC1DE                  |
| COM(1)             | COMDE                  |
| Trigger (1)        | TDE                    |

Of which 1 is for TIM15 only.

### 23.2.25 Debug Mode

When the microcontroller enters debug mode (Cortex-M4F core stops), according to the setting of DBG\_TIMx\_STOP in the DBG module,

The TIMx counter may either continue normal operation or stop. See subsequent DBG sections for details.

### 23.2.26 TIM15/TIM16/TIM17 Interrupt

| Interrupt event   | Event flag | Interrupt enable control bit |
|-------------------|------------|------------------------------|
| update            | UIF        | UIE                          |
| Compare/Capture 1 | CC1IF      | CC1IE                        |
| Compare/Capture 2 | CC2IF      | CC2IE                        |
| COM               | COMIF      | COMIE                        |
| Trigger           | TIF        | TIE                          |
| Brake             | BIF        | BIE                          |

## 23.3 TIM15 registers

| 6: 4   | MMS      | RW  | 3'h0        | Main mode selection (Master mode selection)<br>For selecting synchronization information (TRGO) to be sent to the slave timer in master mode. The combination is as follows:<br>000: Reset-The UG bit of the TIMx_EGR register is used as a trigger output (TRGO). If the reset is generated by the trigger input (the slave mode controller is in reset mode), the signal on the TRGO will have a delay relative to the actual reset.<br>001: Enable-Counter enable signal CNT_EN may be used as a trigger output (TRGO). It is useful to start several timers at the same time or to control a window in which a slave timer is enabled. The Counter Enable signal is generated by a logic AND between CEN control bit and the trigger input when configured in gated mode. When the counter enable signal is controlled by the trigger input, there is a delay on the TRGO unless the master/slave mode is selected (see description of the MSM bit in the TIMx_SMCR register).<br>010: Update-The update event is selected as Trigger Output (TRGO). For instance a master timer can then be used as a prescaler for a slave timer.<br>011: Comparison Pulse-When a capture occurs or a comparison is successful, when the CC1IF flag is to be set (even if it is already high), the trigger output sends a positive pulse (TRGO).<br>100: Compare - OC1REFC signal is used as trigger output (TRGO)<br>101: Compare - OC2REFC signal is used as trigger output (TRGO)<br>Other: Reserved<br>Note:<br>1. The clock of the slave timer or ADC must be enabled prior to receive events from the master timer, and must not be changed.<br>2. If the master and slave timers are not on the same bus, the master mode should be configured to the width that can be picked by the slave timer. |

|   |       |    |   | <p>These bits define the action of outputting the reference signal OC1REF, and OC1REF determines the values of OC1, OC1N. OC1REF is active high whereas OC1 and OC1N active level depends on CC1P and CC1NP bits.</p> <p>0000: Frozen. The comparison between the output compare register TIMx_CCR1 and the counter TIMx_CNT has no effect on the outputs.</p> <p>0001: Set channel 1 to active level on match. When the value of counter TIMx_CNT is the same as that of capture/compare register 1 (TIMx_CCR1), OC1REF is forced to be high.</p> <p>0010: Set channel 1 to inactive level on match. OC1REF signal is forced low when the counter TIMx_CNT matches the capture/compare register 1 (TIMx_CCR1).</p> <p>0011: Toggle OC1REF toggles when TIMx_CNT=TIMx_CCR1.</p> <p>0100: Force inactive level OC1REF is forced low.</p> <p>0101: Force active level OC1REF is forced high.</p> <p>0110: PWM Mode 1-On up count, channel 1 is active once TIMx_CNT &lt; TIMx_CCR1, otherwise it is invalid; On counting down, channel 1 is an inactive level (OC1REF = 0) once TIMx_CNT &gt; TIMx_CCR1, otherwise it is an active level (OC1REF = 1).</p> <p>0111: PWM Mode 2-On up count, channel 1 is invalid level once TIMx_CNT &lt; TIMx_CCR1, active level otherwise; When counting down, channel 1 is active once TIMx_CNT &gt; TIMx_CCR1, otherwise it is invalid.</p> <p>1000: Retriggerable OPM Mode 1-In incremental count mode, the channel is active until a trigger event (tim_trgi signal) is detected. Then, the comparison is performed as in PWM mode 1, and the channel becomes valid again at the next update. In decrement count mode, the channel is invalid until a trigger event (tim_trgi signal) is detected. Then, the comparison is performed as in PWM Mode 1, and the channel becomes invalid again at the next update</p> <p>1001: Retriggerable OPM Mode 2-In incremental count mode, the channel is in an invalid state until a trigger event (tim_trgi signal) is detected. Then, the comparison is performed as in PWM mode 2, and the channel becomes invalid again at the next update. In the decrement count mode, the channel is in an active state until a trigger event (tim_trgi signal) is detected. Then, the comparison is performed as in PWM Mode 2, and the channel becomes active again at the next update</p> <p>1010: Reserved</p> <p>1011: Reserved</p> <p>1100: Combined PWM Mode 1-OC1REF has the same behavior as in PWM Mode 1, OC1REFC is composed of OC1REF and OC2REF or logic</p> <p>1101: Combined PWM Mode 2-OC1REF has the same behavior as in PWM Mode 2, OC1REFC is composed of OC1REF and OC2REF AND logic</p> <p>1110: Reserved</p> <p>1111: Reserved</p> <p>Note: These bits can not be modified as long as LOCK level 3 has been programmed (LOCK bits in TIMx_BDTR register) and CC1S='00' (the channel is configured in output).</p> <p>Note 2: In PWM mode, the OC1REF level is changed only when the comparison result is changed or when the output comparison mode is switched from freeze mode to PWM mode.</p> <p>Note 3: This bit segment can be preloaded when the channel has complementary outputs. If the CCPC position of TIMx_CR2 is 1, then the OC1M valid bit is updated with a new value from the preload only when the COM event is generated</p> |
| 3 | OC1PE | RW | 0 | <p>Output Comparison 1 Preload Enable Output Compare 1 preload enable</p> <p>0: The preload function of the TIMx_CCR1 register is disabled, the TIMx_CCR1 register can be written at any time, and the newly written value takes effect immediately.</p> <p>1: Turn on the preload function of the TIMx_CCR1 register. Read and write operations only operate on the preload register. The preload value of TIMx_CCR1 is loaded into the current register when the update event arrives.</p> <p>Note: These bits can not be modified as long as LOCK level 3 has been programmed (LOCK bits in TIMx_BDTR register) and CC1S='00' (the channel is configured in output).</p> <p>Note 2: Only in monopulse mode (OPM = 1 of TIMx_CR1 register), PWM mode can be used without confirming the preload register, otherwise its operation is uncertain.</p>                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |

|      |      |    |      | <p>This bit is used to speed up the output response to the triggering input event. Must be used in single pulse mode (OPM position 1 of the TIMx_CR1 register) to achieve fast pulse output when the trigger comes.</p> <p>0: CC1 behaves normally depending on counter and CCR1 values even when the trigger is ON. The minimum delay to activate CC1 output when an edge occurs on the trigger input is 5 clock cycles.</p> <p>1: An active edge on the trigger input acts like a compare match on OC1 output. Then, OC1 is set to the compare level independently from the result of the comparison. Delay to sample the trigger input and to activate CC1 output is reduced to 3 clock cycles. Only available for PWM Mode 1 and PWM Mode 2</p> |
| 1: 0 | CC1S | RW | 2'h0 | <p>Capture/Compare 1 selection</p> <p>These 2 bits define the direction of the channel (input/output), and the selection of the input pin:</p> <p>00: CC1 channel is configured as output;</p> <p>01: CC1 channel is configured as input, IC1 is mapped on TI1.</p> <p>10: CC1 channel is configured as input, IC1 is mapped on TI2;</p> <p>11: CC1 channel is configured as input, IC1 is mapped on TRC. This mode only operates when the internal flip-flop input is selected (selected by the TS bit of the TIMx_SMCR register).</p> <p>Note: CC1S is writable only when the channel is closed (CC1E = 0 in the TIMx_CCER register).</p>                                                                                                         |

### 23.3.7.2 Input capture mode:

|  |   |  |   |   |                                                                                                                                                                                                                                                                              |
|--|---|--|---|---|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|  | 1 |  | 1 | 1 | Then if the clock exists (only valid when brake 1 is triggered, brake 2 is not needed): OCx = OISx, OCxN = OISxN after a dead time, assuming that OISx and OISxN do not both correspond to the effective levels of OCx and OCxN<br>Note: Brake 2 is only for OSSI = OSSR = 1 |
|--|---|--|---|---|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

In particular, when the dead band is active, the output is always output according to the rules of dead band output, although moe may have been set to 1 by software or hardware at this time.

If neither of the two outputs of a channel is used (CCxE = CCxNE = 0), then OISx, OISxN, CCxP, and CCxNP must all be cleared.

| 6: 4  | OC1M     | RW  | 3'h0        | Output Comparison 1 Mode Output Compare 1 mode<br>These bits define the behavior of the output reference signal OC1REF from which OC1 and OC1N are derived. OC1REF is active high whereas OC1 and OC1N active level depends on CC1P and CC1NP bits.<br>000: Frozen. The comparison between the output compare register TIMx_CCR1 and the counter TIMx_CNT has no effect on the outputs.<br>001: Set channel 1 to active level on match. When the value of counter TIMx_CNT is the same as that of capture/compare register 1 (TIMx_CCR1), OC1REF is forced to be high.<br>010: Set channel 1 to inactive level on match. OC1REF signal is forced low when the counter TIMx_CNT matches the capture/compare register 1 (TIMx_CCR1).<br>011: Toggle OC1REF toggles when TIMx_CNT=TIMx_CCR1.<br>100: Force inactive level OC1REF is forced low.<br>101: Force active level OC1REF is forced high.<br>110: PWM mode 1-on up count, channel 1 is active once TIMx_CNT < TIMx_CCR1, otherwise it is invalid; On counting down, channel 1 is an inactive level (OC1REF = 0) once TIMx_CNT > TIMx_CCR1, otherwise it is an active level (OC1REF = 1).<br>111: PWM mode 2 - In upcounting, channel 1 is inactive as long as TIMx_CNT<TIMx_CCR1 else active. In downcounting, channel 1 is active as long as TIMx_CNT>TIMx_CCR1 else inactive.<br>Note: These bits can not be modified as long as LOCK level 3 has been programmed (LOCK bits in TIMx_BDTR register) and CC1S='00' (the channel is configured in output).<br>Note: In PWM mode 1 or 2, the OCREF level changes when the result of the comparison changes or when the output compare mode switches from frozen to PWM mode. |
| 3     | OC1PE    | RW  | 0           | Output Comparison 1 Preload Enable Output Compare 1 preload enable<br>0: The preload function of the TIMx_CCR1 register is disabled, the TIMx_CCR1 register can be written at any time, and the newly written value takes effect immediately.<br>1: Turn on the preload function of the TIMx_CCR1 register. Read and write operations only operate on the preload register. The preload value of TIMx_CCR1 is loaded into the current register when the update event arrives.<br>Note: These bits can not be modified as long as LOCK level 3 has been programmed (LOCK bits in TIMx_BDTR register) and CC1S='00' (the channel is configured in output).<br>Note 2: Only in monopulse mode (OPM = 1 of TIMx_CR1 register), PWM mode can be used without confirming the preload register, otherwise its operation is uncertain.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
| 2     | OC1FE    | RW  | 0           | Output Compare 1 Fast Enable (Output Compare 1 fast enable)<br>This bit is used to speed up the output response to the triggering input event. Must be used in single pulse mode (OPM position 1 of the TIMx_CR1 register) to achieve fast pulse output when the trigger comes.<br>0: CC1 behaves normally depending on counter and CCR1 values even when the trigger is ON. The minimum delay to activate CC1 output when an edge occurs on the trigger input is 5 clock cycles.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |

In particular, when the dead band is active, the output is always output according to the rules of dead band output, although moe may have been set to 1 by software or hardware at this time.

If neither of the two outputs of a channel is used (CCxE = CCxNE = 0), then OISx, OISxN, CCxP, and CCxNP must all be cleared.

## 24. Basic Timer (TIM6 and TIM7)

### 24.1 Introduction

The base timers TIM6 and TIM7 each contain a 16-bit autoloader counter driven by their respective programmable prescalers.

They can provide a time reference as a general purpose timer, and in particular can provide a clock for a digital-to-analog converter (DAC). In fact, the timers are internally connected to the DAC and are able to drive it through their trigger outputs.

TIM6 and TIM7 are completely independent, they do not share any resources.

#### 24.1.1 TIM6 and TIM7 Main Features

The main functions of the TIM6 and TIM7 timers include:

- 16-bit auto-load counter
- 16-bit programmable (can be modified in real time) prescaler, the frequency division coefficient of the counter clock frequency is any value between 1 and 65535
- DAC synchronous circuit is triggered.
- Generate interrupt/DMA when an update event (counter overflow) occurs

#### 24.1.2 CAN block diagram

## 24.2 TIMx functional description

### 24.2.1 Time-base unit

The main block of the programmable advanced-control timer is a 16-bit counter with its related auto-reload register. This counter can count up. The clock of the counter may be divided by a prescaler. The counter, the auto-reload register and the prescaler register can be written or read by software. This is true even when the counter is running.

The time base unit comprises:

- Counter Register (TIMx\_CNT)
- Prescaler Register (TIMx\_PSC)
- Autoload Register (TIMx\_ARR)

An autoloader register is preloaded, and a write or read autoloader register will access its preload register. The contents of the preload register are transferred to the shadow register either immediately or at each update event (UEV), depending on the setting of the Autoload preload enable bit (ARPE) in the TIMx\_CR1 register. An update event occurs when the counter reaches an overflow condition and when the UDIS bit in the TIMx\_CR1 register is equal to 0. The update event may also be generated by software and other conditions. The generation of update events under each configuration will be described in detail later.

The counter is driven by the clock output CK\_CNT divided by the prescaler, which is valid for the counter only when the counter enable bit (CEN) in the TIMx\_CR1 register is set. (See the description of the slave mode controller for more details on enabling counters).

Note that the counter starts counting 1 clock cycle after setting the CEN bit in the TIMx\_CR register.

#### Prescaler description

The prescaler can divide the clock frequency of the counter by any value between 1 and 65536. It is a 16-bit counter controlled based on a 16-bit register (in the TIMx\_PSC register). It can be changed on the fly as this control register is buffered. The new prescalation parameters will be adopted when the next update event comes.

The following figures give examples of changing counter parameters when the prescaler is running.

Figure 24-1 Timing diagram of the counter when the parameters of the prescaler change from 1 to 2

Figure 24-2 Timing diagram of the counter when the parameter of the prescaler is changed from 1 to

4

## 24.2.2 Counter mode

### Upcounting mode

In the count-up mode, the counter counts from 0 to the auto-load value (the content of TIMx\_ARR), then counts from 0 again and generates a count overflow event.

Setting the UG bit in the TIMx\_EGR register (either by software or using a slave mode controller) can also generate an update event.

The UEV event can be disabled by software by setting the UDIS bit in the TIMx\_CR1 register. This is to avoid updating the shadow registers while writing new values in the preload registers. No update event will be generated until the UDIS bit is cleared '0'. Even so, when an update event should occur, the counter is still cleared '0', and the counter inside the prescaler is also cleared '0' (but the value of the prescaler remains unchanged).

In addition, if the URS bit in the TIMx\_CR1 register is set (select the update request source), an update event UEV can be generated by setting the UG bit, but the UIF flag bit will not be set (i.e., no interrupt request will be generated). This is to avoid generating both update and capture interrupts when clearing the counter on the capture event.

When an update event occurs, all of the following registers are updated, and the hardware sets an update flag bit (UIF bit in the TIMx\_SR register) at the same time (according to the URS bit):

- The auto-load shadow register is updated with the preload value (TIMx\_ARR).
- The buffer of the prescaler is reloaded with the preload value (content of the TIMx\_PSC register).

The following figures show some examples of the counter behavior for different clock frequencies when TIMx\_ARR=0x36.

Figure 24-3 counter timing diagram with internal clock division factor of 1

Figure 24-4 counter timing diagram with internal clock division factor of 2

Figure 24-5 Counter timing diagram, internal clock divided by 4

Figure 24-6 Counter timing diagram, internal clock divided by N

Figure 24-7 Counter timing diagram, update event when ARPE=0 (no TIMx\_ARR preloaded)

Figure 24-8 Counter timing diagram, update event when ARPE=1 (TIMx\_ARR preloaded)

### 24.2.3 Debug mode

When the microcontroller enters the debug mode (Cortex-M4F core stops), the TIMx counter may either continue normal operation or stop according to the setting of DBG\_TIMx\_STOP in the DBG module. See subsequent DBG sections for details.

## 24.3 TIMx registers

### 24.3.1 TIM6 and TIM7 control register 1 (TIMx\_CR1)

Address offset: 0x00

Reset value: 0x0000

| 6: 4  | MMS      | RW  | 0           | <p>Main mode selection (Master mode selection)</p> <p>These 3 bits are used to select synchronization information (TRGO) to be sent to the slave timer in master mode. The combination is as follows:</p> <p>000: Reset-The UG bit of the TIMx_EGR register is used as a trigger output (TRGO). If the reset is generated by the trigger input (the slave mode controller is in reset mode), the signal on the TRGO will have a delay relative to the actual reset.</p> <p>001: Enable-Counter enable signal CNT_EN is used as a trigger output (TRGO). It is useful to start several timers at the same time or to control a window in which a slave timer is enabled. The Counter Enable signal is generated by a logic AND between CEN control bit and the trigger input when configured in gated mode. When the counter enable signal is controlled by the trigger input, there is a delay on the TRGO unless the master/slave mode is selected (see description of the MSM bit in the TIMx_SMCR register).</p> <p>010: Update - The update event is selected as trigger output (TRGO). For instance a master timer can then be used as a prescaler for a slave timer.</p> <p>Note: The clock of the slave timer or ADC must be enabled prior to receive events from the master timer, and must not be changed.</p> |

## 25. Low-power timer (LPTIM)

### 25.1 Introduction

PTIM is a 16-bit timer. Due to its diversity of clock sources, LPTIM is able to maintain operation in all power consumption modes except standby mode. Considering that LPTIM can operate even without an internal clock source, it can be used as a pulse counter, which is useful in some applications. LPTIM introduces a flexible clocking scheme that delivers the required functionality and performance while minimizing power consumption.

#### 25.1.1 Main features

- 16 bit upcounter
- 3-bit prescaler with 8 possible division factors (1, 2, 4, 8, 16, 32, 64, 128)
- Selectable clock
  - Internal clock source: APB clock or any other oscillator (see RCC section)
  - External clock source via LPTIM input (works without running an embedded oscillator, used by the pulse counter application).
- 16-bit ARR reloadable register
- 16-bit comparison register
- Continuous/One-shot mode
- Optional software/hardware input trigger
- Configurable digital glitch filter
- Configurable outputs: Pulse, PWM
- Configurable IO polarity
- Encoder Mode

## 25.3 LPTIM functional description

### 25.3.1 Reset and Clock

Through the RCC module, the LPTIM can be clocked using an internal clock signal. Multiple clock sources may be used to provide clocks for the LPTIM. It can be timed using an internal clock signal, which can be a PCLK (APB clock) or any other oscillator selectable via RCC. Furthermore, the LPTIM may be clocked by an external clock source Input1. When counting with an external clock source, LPTIM may run in one of two configurations:

- The first configuration is that the LPTIM is clocked by an external signal, but at the same time an internal clock signal is supplied to the LPTIM from the PCLK or any other oscillator.
- The second configuration is when the LPTIM is separately clocked by an external clock source through its external Input1. This configuration is used to implement the timeout function or pulse counter function when all oscillators are turned off after entering the low power mode.

Programming the CKSEL bit controls whether the LPTIM uses an external or internal clock source. When configured to use an external clock source, the CKPOL bit is used to select an external clock signal active edge.

### 25.3.2 Glitch filter

The LPTIM inputs, whether external (mapped to the GPIO) or internal (mapped to other embedded peripherals at the chip level), are protected by digital filters that prevent any glitches and noise disturbances from propagating inside the LPTIM. This is to prevent false counts or triggers. Before activating the digital filter, an internal clock source should first be provided to the LPTIM. This is necessary to guarantee the proper functioning of the filter. The digital filters are divided into two groups:

- The first set of digital filters protects the LPTIM external input. The sensitivity of the digital filter is controlled by CKFLT bit
- A second set of digital filters protects the LPTIM internal trigger inputs. The digital filter sensitivity is controlled by the TRGFLT bit.

Note: Digital filter sensitivity is controlled by banks. It is not possible to configure each digital filter sensitivity individually within the same group.

The filter sensitivity acts on the number of successive equal samples detected on an input of the LPTIM to treat the signal level change as a valid transition. The figure below shows an example of the glitch filter behavior in the case of programming 2 consecutive samples.

If no internal clock signal is provided, the digital filter must be deactivated by setting the CKFLT and TRGFLT bits to "0". In this case, an external analog filter can be used to protect the LPTIM external input from glitch interference.

### 25.3.3 Prescaler

The LPTIM 16-bit counter is preceded by a configurable power-of-2 prescaler. The prescaler division ratio is controlled by LPTIM\_CFGR.PRESC [2: 0].

The table below lists all the possible division ratios:

| Programming | Dividing factor |
|-------------|-----------------|
| 000         | /1              |
| 001         | /2              |
| 010         | /4              |
| 011         | /8              |
| 100         | /16             |
| 101         | /32             |
| 110         | /64             |
| 111         | /128            |

### 25.3.4 Trigger selection

The LPTIM counter can be started by software or after detecting a valid edge of one of the 6 (optional maximum number of inputs) trigger inputs.

TRIGEN [1: 0] is used to determine the LPTIM trigger source:

When TRIGEN [1: 0] equals "00", the LPTIM counter starts once one of the CNTSTRT or SNGSTRT bits is set by the software. The three remaining possible values of TRIGEN [1: 0] are used to configure the valid edge used by the trigger input. Once a valid edge is detected, the LPTIM counter starts.

When TRIGEN [1: 0] is not '00', TRIGSEL [2: 0] is used to select which of the trigger inputs is used to start the counter.

External triggers are treated as asynchronous signals for LPTIM. Therefore, after the trigger detection, due to the synchronization, a delay of two counter clock cycles is required before the timer starts running.

If a new trigger event occurs when the timer has already started, it will be ignored (unless the timeout feature is enabled).

The timer must be enabled before setting the SNGSTRT/CNTSTRT bit. When the timer is disabled, any writes to these bits will be discarded by the hardware.

When the counter is started via software (TRIGEN [1: 0] = 00), there is a delay of 3 count clock cycles between the LPTIM\_CR register update (setting one of the SNGSTRT or CNTSTRT bits) and the effective start of the counter.

### 25.3.5 Mode of operation

LPTIM has two operating modes as follows:

- Continuous counting mode: The timer runs freely, starts from the trigger event, and does not stop until the timer is disabled.
- Single count mode: The timer starts with a trigger event and stops when the ARR value is reached.

#### 25.3.5.1 Single count mode

To enable single count, the LPTIM\_CR.SNGSTRT bit must be set to 1.

If External Trigger is selected, an external event that arrives after the SNGSTRT bit is set and the counter stops (containing zero values), starts the counter for a new single counting cycle, as shown in the following figure.

A new trigger event will re-start the timer. Any trigger events are ignored after the counter is started and until the ARR is reached.

-Activate setting mode once

When LPTIM\_CFGR.WAVE position 1, the one-time setting mode is activated. In this case, the counter is only started once after the first trigger, and any subsequent trigger events are ignored. As shown in the following image:

In case of software start (TRIGEN [1: 0] = '00'), the SNGSTRT set starts the counter for a single count.

### 25.3.5.2 Continuous counting mode

To enable the continuous counting, the LPTIM\_CR.CNTSTRT bit must be set.

If external trigger is selected, external trigger events that arrive after CNTSTRT is set will start the counter for continuous counting. Any subsequent externally triggered events will be discarded as shown in the image below.

In case of software startup (TRIGEN [1: 0] = '00'), setting CNTSTRT starts the counter for continuous counting.

The LPTIM\_CR.SNGSTRT and LPTIM\_CR.CNTSTRT bits can only be set when the timer is enabled (LPTIM\_CR.ENABLE is '1'). You can quickly change from single mode to continuous mode:

- If the Continuous mode was previously selected, setting SNGSTRT will switch the LPTIM to the One-shot mode. The counter (if it starts counting) stops as soon as it reaches ARR.
- If the One-shot mode was previously selected, setting LPTIM\_CR.CNTSTRT will switch the LPTIM to the Continuous mode. The counter (if it starts counting) will restart as soon as it reaches ARR.

### 25.3.5.3 Waveform generation

Two 16-bit registers, LPTIM\_ARR (Automatic Reload Register) and LPTIM\_CMP (Comparison Register), are used to generate several different waveforms on the LPTIM output.

The timer can generate the following waveforms:

- PWM mode: The LPTIM output is set when the counter value in LPTIM\_CNT exceeds the comparison value in LPTIM\_CMP. Once a match occurs between the LPTIM\_ARR and LPTIM\_CNT registers, the LPTIM output is reset.
- Single pulse mode: The output waveform is similar to the PWM mode of the first pulse, and then the output is permanently reset.
- Once set mode: The output waveform is similar to monopulse mode, except that the output will remain at the last signal level (depending on the polarity of the output configuration).

The above mode requires that the LPTIM\_ARR register value be strictly greater than the LPTIM\_CMP register value.

The LPTIM output waveform can be configured via the WAVE bit as follows:

- Resetting the WAVE bit to "0" forces LPTIM to generate either a PWM waveform or a monopulse waveform, depending on which bit is set: CNTSTRT or SNGSTRT.
- Setting the WAVE bit to "1" forces LPTIM to generate a set mode waveform once.

The WAVPOL bit controls the LPTIM output polarity. Changes take effect immediately, so the output defaults will change immediately after reconfiguring the polarity, even before enabling the timer.

A signal can be generated with a frequency up to the LPTIM clock frequency divided by 2. The figure below shows three possible waveforms that can be generated on the LPTIM output. Furthermore, it shows the effect of changing polarity using WAVPOL bits.

### 25.3.6 Register update

The LPTIM\_ARR register and the LPTIM\_CMP register are updated immediately after the APB bus write operation, or at the end of the current counting period if the timer has been started. The PRELOAD bit controls how the LPTIM\_ARR register is updated:

When the PRELOAD bit is reset to "0", the LPTIM\_ARR register is updated immediately after any write access.

When the PRELOAD bit is set to "1", the LPTIM\_ARR register will be updated at the end of the current counting period if the timer has been started.

The LPTIM APB interface and the LPTIM kernel logic use different clocks, so there is some delay between the moment when the APB is written and the moment when these values are available for the counter comparator. Any additional writes to these registers must be avoided during this delay period.

The ARROK flag and the CMPOK flag in the LPTIM\_ISR register indicate a write operation completion flag to the LPTIM\_ARR register and the LPTIM\_CMP register, respectively.

After writing to the LPTIM\_ARR register or the LPTIM\_CMP register, a new write operation can be performed to the same register only after the previous write operation is completed. Any successive writes before the ARROK or CMPOK flag position bit will result in unpredictable results.

### 25.3.7 Counter mode

The LPTIM counter can be used to count external events on LPTIM Input1 and can also be used to count internal clock cycles. The CKSEL bit controls which source will be used to update the counter. If LPTIM is configured to count external events on Input1, the counter can be updated on the rising, falling, or double edges depending on the value written to the CKPOL [1: 0] bit.

Depending on the value of CKSEL, the following counting modes can be selected:

CKSEL = 0: LPTIM is timed by internal clock source

The LPTIM clock is provided by an internal clock source, and the LPTIM counter is configured to update after each internal clock pulse.

CKSEL = 1: LPTIM is clocked by an external clock source.

In this configuration, LPTIM does not require an internal clock source (clock glitch filtering is not supported in this mode). The signal injected on Input1 external to the LPTIM is used as the clock of the LPTIM. This configuration is suitable for operating modes where the embedded oscillator is not enabled.

For this configuration, the LPTIM counter can be updated at the rising or falling edge of the input1 clock signal, but not at the same time. Since the signal injected on Input1 outside the LPTIM is also used to clock the LPTIM kernel logic, there is some initial delay before the counter is incremented (after LPTIM is enabled).

### 25.3.8 Timer enable

The LPTIM\_CR.ENABLE bit is used to enable/disable LPTIM kernel logic. After the ENABLE bit is set, two counter clocks need to be delayed to ENABLE LPTIM.

The LPTIM\_CFGR and LPTIM\_IER registers must be modified only when the LPTIM is disabled.

### 25.3.8.1 Encoder Mode

This mode allows processing of signals from the quadrature encoder used to detect the angular position of the rotating element. The encoder interface mode simply acts as an external clock with directional selection. This means that the counter just counts continuously between 0 and ARR values (0 to ARR or ARR to 0, depending on the direction). Therefore, LPTIM\_ARR must be configured before startup. A clock signal is generated from two external input signals Input1 and Input2 to clock the LPTIM counter. The phase between these two signals determines the counting direction.

The encoder mode is only available when the LPTIM is counted by the internal clock source. The signal frequency on the Input1 and Input2 inputs must not exceed 1/4 of the LPTIM internal clock. This is a mandatory requirement to ensure the proper operation of LPTIM.

The direction change is indicated by two down and up flags in the LPTIM\_ISR register. In addition, if the DOWNIE/UPIE bit is enabled, an interrupt can be generated for both direction change events.

To activate encoder mode, the ENC bit must be set to "1". The LPTIM must first be configured in Continuous mode.

When the encoder mode is active, the LPTIM counter is automatically modified according to the speed and direction of the incremental encoder. Therefore, its contents always represent the position of the encoder. The counting direction indicated by the UP and DOWN flags corresponds to the rotational direction of the encoder rotor.

Different counting cases may occur depending on the edge sensitivity of the CKPOL [1: 0] bit configuration. The table below summarizes the possible combinations, assuming that Input1 and Input2 do not switch at the same time.

| Effective edge | Reverse signal level<br>(Input1 for Input2, Input2 for Input1) | Input1 signal |         | Input2 signal |         |
|----------------|----------------------------------------------------------------|---------------|---------|---------------|---------|
|                |                                                                | Rising        | Falling | Rising        | Falling |
| rising edge    | High                                                           | Minus         | -       | Add           | -       |
|                | Low                                                            | Add           | -       | Minus         | -       |
| falling edge   | High                                                           | -             | Add     | -             | Minus   |
|                | Low                                                            | -             | Minus   | -             | Add     |
| Double edge    | High                                                           | Minus         | Add     | Add           | Minus   |
|                | Low                                                            | Add           | Minus   | Minus         | Add     |

The figure below shows the count sequence for an encoder mode configured with dual-edge sensitivity. In this mode, the LPTIM must be clocked by an internal clock source, so the CKSEL bit must maintain its reset value of 0. In addition, the prescaler division ratio must be equal to its reset value of 1 (the PRESC [2: 0] bit must be "000").

### 25.3.9 Debug mode

When the microcontroller enters debug mode (core halted), the LPTIM counter either continues to work normally or stops, depending on the DBG\_LPTIM\_STOP configuration bit in the DBG module.

### 25.3.10 LPTIM low-power modes

| Mode            | Description                                                                                                            |
|-----------------|------------------------------------------------------------------------------------------------------------------------|
| Sleep           | No impact. LPTIM interrupts cause the device to exit Sleep mode.                                                       |
| Low-power run   | No impact.                                                                                                             |
| Low-power sleep | No impact. The LPTIM interrupt causes the device to exit low power sleep mode.                                         |
| Stop0/Stop1     | There is no effect when LPTIM is timed by LSE or LSI. The LPTIM interrupt causes the device to exit Stop 0 and Stop 1. |
| Standby         | The LPTIM peripheral is powered down and must be reinitialized after exiting standby or shutdown mode.                 |
| Shutdown        |                                                                                                                        |

Note: When using Lptim wakeup, it is necessary to ensure that the interval between two wakeups is greater than 6 PCLK cycles, otherwise it will lead to unpredictable results.

### 25.3.11 LPTIM interrupts

The following events generate an interrupt/wake-up event, if they are enabled through the LPTIM\_IER register:

- Compare Match
- Automatic reload match (regardless of orientation if encoder mode)
- External trigger event
- Automatic reload register write complete
- Compare register write complete
- Direction change (encoder mode), programmable (up/down/both).

Note: If the corresponding bit in the LPTIM\_IER register (interrupt enable register) is set to 1 after the corresponding flag in the LPTIM\_ISR register (status register) is set to 1, no interrupt will occur.

| Interrupt event                          | Description                                                                                                                                     |
|------------------------------------------|-------------------------------------------------------------------------------------------------------------------------------------------------|
| Compare Match                            | An interrupt flag is generated when the contents of the counter register (LPTIM_CNT) match the contents of the comparison register (LPTIM_CMP). |
| Auto-reload match                        | Interrupt flag is raised when the content of the Counter register (LPTIM_CNT) matches the content of the Auto-reload register (LPTIM_ARR).      |
| External trigger event                   | When an external trigger event is detected, the interrupt flag is set                                                                           |
| Automatic reload register write complete | An interrupt flag is generated when a write operation to the LPTIM_ARR register is completed.                                                   |

|                                 |                                                                                                                                                                                                                                                                                        |
|---------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| Compare register write complete | An interrupt flag is generated when a write operation to the LPTIM_CMP register is completed.                                                                                                                                                                                          |
| Change of direction             | Used in encoder mode. Two interrupt flags are embedded to indicate a change of direction: <ul style="list-style-type: none"> <li>— The UP flag indicates a change in increment count direction</li> <li>— The DOWN flag indicates that the count DOWN direction has changed</li> </ul> |

## 25.4 TIMx registers

#### 25.4.4 LPTIM configuration register, Address = 0x0C (LPTIM\_CFGR)

Address offset: 0x00C

Reset value: 0x0000 0000

When configuring this register, you need to set the required registers at once.

### 25.4.5 LPTIM Control Register, Address = 0x10 (LPTIM\_CR)

Address offset: 0x010

Reset value: 0x0000 0000

After configuring LPTIM1EN/LPTIM2EN of the RCC module, program LPTIM\_CFGR.TRIGEN immediately, and then wait for 5 kernal clocks before configuring SNGSTRT or CNTSTRT of this register.

## 26. Infrared interface (IRTIM)

An infrared interface (IRTIM) for remote control is integrated into the chip. It can realize the function of remote control together with an infrared LED. It uses the internal connection of TIM16 and TIM17 as shown in the figure below.

In order to generate the infrared remote control signal, the Infrared interface must be turned on and channel 1 (TIM16\_OC1) of TIM16 and channel 1 (TIM17\_OC1) of TIM17 must be properly configured to generate the correct waveform.

The infrared receiver can be easily implemented through a basic input capture mode.

All standard infrared pulse modulation modes can be obtained by programming the output comparison channels of the two timers.

TIM 17 is used to generate a high frequency carrier signal, while TIM 16 may generate a modulation envelope.

The infrared function is output to the IR\_OUT pin, and the activation of this function is achieved by enabling the associated multiplexing function bit of the GPIO\_AFRx register.

The LED requires a large sink current driving capability (only at the PB9/PA13pin), which can be activated through the I2C1\_FMP bit of the SYSCFG\_CFGR1 register, which is enough to support the direct control of the large sink current of the infrared LED.

Figure 26-1 IRTIM internal connection diagram

## 27. Real-time clock (RTC)

### 27.1 Overview

The RTC is an independent counter. The RTC provides a set of continuously running counters which can be used, with suitable software, to provide a clock-calendar function. The counter values can be written to set the current time/date of the system.

The RTC module and the clock configuration system (RCC\_BDCR register) are in the backup domain, i.e. the setting and time of the RTC remain unchanged after the system resets or wakes up from standby mode.

After the system reset, access to the backup registers and RTC is disabled to prevent accidental write operations to the backup domain (BKP). Doing the following will enable access to the backup registers and RTC:

- Set the PWREN and BKPEN bits of register RCC\_APB1ENR to enable power and backup interface clocks
- Sets the DBP bit of the register PWR\_CR to enable access to the backup register and RTC.

### 27.2 Main features

The DMA supports:

- Programmable pre-division coefficient: The division coefficient is up to 220.
- 32-bit programmable counter, which can be used for measurement of longer time periods.
- 2 separate clocks: PCLK1 and RTC clocks for the APB1 interface (the frequency of the RTC clock must be less than a quarter of the PCLK1 clock frequency).
- The RTC clock source could be any of the following ones:
  - 128 division of the HSE clock;
  - LSE oscillator clock;
  - LSI oscillator clock
- Two separate reset types:
  - The APB1 interface is reset by the system;
  - RTC cores (prescalers, alarms, counters, and dividers) can only be reset by the backup domain.
- 2 dedicated maskable interrupts:
  - Alarm interrupt, used to generate a software-programmable alarm interrupt.
  - RTC global interrupts, including second interrupts, alarm clock interrupts, and overflow interrupts.

## 27.3 Functional description

### 27.3.1 Overview

Figure 27-1 RTC functional block diagram

The RTC consists of two main parts (see figure above). The first part (APB1 interface) is used to connect to the APB1 bus. This unit also contains a set of 32-bit registers (RTC\_CR, registers actually scattered at two addresses), which can be read and written through the APB1 bus. The APB1 interface is driven by the APB1 bus clock and is used to connect to the APB1 bus.

The other unit (RTC Core) consists of a chain of programmable counters made of two main blocks. The first module is the prescaler module of the RTC, which is programmable to produce an RTC time reference TR\_CLK of up to 1 second. It includes a 20-bit programmable divider (RTC prescaler). If the corresponding allow bit is set in the RTC\_CR register, RTC generates an interrupt (second interrupt) in each TR\_CLK cycle.

The second block is a 32-bit programmable counter that can be initialized to the current system time. The system time is accumulated in TR\_CLK cycles and compared to the programmable time stored in the RTC\_ALR register. If the corresponding allow bit is set in the RTC\_CR control register, an alarm interrupt will be generated when the comparison matches.

The alarm interrupt serves as a wake-up signal for the standby mode and the stop mode. The picture above shows the situation in standby mode, after waking up from standby mode. In stop mode, the RTC alarm clock needs to be configured as a wake-up EXTI line17 corresponding register.

### 27.3.2 Register reset

The RTC\_PRL, RTC\_ALR, RTC\_CNT, and RTC\_DIV registers can only be reset by the backup domain reset signal. Other system registers (RTC\_CR) are reset asynchronously by system reset or power reset.

### 27.3.3 Reading RTC registers

The RTC core is completely independent of the RTC APB1 interface.

The software accesses the prescalation values, counter values and alarm clock values of RTC through APB1 interface. However, the associated readable register is updated only when the signal after synchronization with the rising edge of the RTC clock to the RTC APB1 clock is valid. This is also true for the RTC flags.

This means that if the APB1 interface has been closed and the read operation is just after APB1 is returned, the RTC register value read from APB1 may be corrupted (usually read to 0) before the first internal register update. This can occur if:

- A system reset or power reset has occurred
- The system just woke up from standby mode

The system just woke up from shutdown mode (in this case the count value just won't update because the CPU doesn't work and the system clock stops but the RTC counts normally and the count value won't sync to the VDDD zone)

In all the above cases, the RTC core remains running when the APB1 interface is disabled (reset, no clock, or power down).

Therefore, if the APB1 interface of the RTC has been disabled when reading the RTC register, the software must first wait for the RSF bit (register synchronization flag) in the RTC\_CR register to be set '1' by the hardware.

Note:

- 1) CPU readable registers include RTC\_CR, RTC\_CNT, RTC\_ALR, and RTC\_DIV;
- 2) The RTC\_CR register is the RTC\_PCLK field, and the CPU can read a stable value at any time;
- 3) RTC\_CNT and RTC\_DIV are derived from the RTC\_CLK domain. After RTC operation, the RTC\_DIV register is updated at the rising edge of each RTC\_CLK; The RTC\_CNT and the flag bits originating from the RTC\_CLK clock domain also use the same update signal as the RTC\_DIV register, although the value of RTC\_CNT does not change every time it is updated;
- 4) In the RTC\_PCLK domain, the RSF is set when the pulse signal after the RTC\_CLK is synchronized to the RTC\_PCLK is valid;
- 5) RSF only controls the read timing of RTC\_CNT and RTC\_DIV (hardware does not control it)

### 27.3.4 Configuring RTC registers

The CNF bit in the RTC\_CR register must be set so that RTC enters configuration mode before writing to the RTC\_PRL, RTC\_CNT, and RTC\_ALR registers.

In addition, writing to any RTC register is only enabled if the previous write operation is finished. It is possible to determine whether the RTC register is being updated by querying the RTOFF status bit in

the RTC\_CR register. A new value can be written to the RTC registers only when the RTOFF status bit value is '1'.

Configuration procedure:

- Querying the RTOFF bit until the value of RTOFF becomes '1'; (indicates that the previous configuration has been completed)
- Set the CNF value to 1 to enter the configuration mode; (At this time, the RTOFF bit is still 1, ensuring that the CPU RTOFF = 1 when writing to the register)
- Performing a write operation to one or more RTC registers; (RTOFF is still 1 in this process, and the RTC\_CLK field register is written to the buffer register in this step)
- Clear the CNF flag bit and exit the configuration mode; (After the hardware detects that CNF is cleared, it starts to perform the register write operation in the previous step and starts to write to the registers in the RTC\_CLK field; At the same time, RTOFF is cleared)
- Poll RTOFF, wait until its value goes to '1' to check the end of the write operation. (The buffer register is written to the RTC\_CLK field after setting RTOFF)

Note: The write operation only executes when the CNF bit is cleared; it takes at least three RTC\_CLK cycles to complete. (3 RTC\_CLK cannot restart the configuration after the CNF flag is cleared, otherwise a configuration error will occur (in this case, it is controlled by RTOFF = 0))

Note:

- 1) In this process, RTOFF = 1 when the CPU writes to the register;
- 2) The write cycle of the CPU is from CNF = 1 to CNF = 0, and other registers are configured between these two operations;
- 3) First write CNF to 1 and then clear CNF. This operation clears RTOFF; RTOFF will not be cleared after only writing CNF = 0 or not clearing after writing CNF = 1;
- 4) First write the CNF to 1 and then clear the CNF. This operation starts the process of writing the buffer register to the RTC\_CLK field register;
- 5) RTOFF is implemented in the RTC\_PCLK domain.

### 27.3.5 RTC Flag Settings

The RTC Second Flag (SECF) is set before changing the RTC counter during each RTC core clock cycle.

In the last RTC clock cycle before the counter reaches 0x0000, the RTC overflow flag (OWF) is set. (OWF is set at the maximum value of detected RTC\_CNT before reaching 0)

The RTC\_Alarm and the RTC alarm flag (ALRF) are set in the RTC clock cycle before the value of the counter reaches the value of the alarm register plus 1 (RTC\_ALR+1). (RTC\_CNT count to RTC\_ALR detected and ALRF set at last RTC\_CLK)

Writes to the RTC alarm register (RTC\_ALR) must be synchronized with the RTC second flag using one of the following procedures:

- Use the RTC alarm interrupt and modify the RTC alarm register (RTC\_ALR) and/or the RTC counter register (RTC\_CNT) in the interrupt handler.
- Wait for the SECF bit in the RTC control register to be set before changing the RTC alarm register (RTC\_ALR) and/or the RTC counter register (RTC\_CNT).

## 27.3.6 RTC timing

### (1) RTC seconds and alarm timing

SECF and ALRF are RTC\_PCLK domain signals, and are generated by sampling RTC\_Second and RTC\_Alarm signals in RTC\_CLK domain, respectively.

### (2) RTC overflow timing

SECF and OWF are RTC\_PCLK domain signals, which are generated by sampling RTC\_CLK domain RTC\_Second and RTC\_Overflow numbers, respectively.

## 27.4 TIMx registers

The register width is 32 bits and only allows word operations.

| 0 | SECIE | RW | 0 | Second interrupt enable<br>0: second interrupt disabled<br>1: second interrupt enabled |

These bits are used to mask interrupt requests. Note that at reset all interrupts are disabled, so it is possible to write to the RTC registers to ensure that no interrupt requests are pending after initialization. It is not possible to write to the RTC\_CRH register when the peripheral is completing a previous write operation.

The RTC functions are controlled by this control register. Some bits must be written using a specific configuration procedure.

|--|--|--|--|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|  |  |  |  | <p>When the 32-bit programmable prescaler overflows, this bit is set '1' by the hardware and the RTC counter is incremented by 1. Therefore, this flag provides a periodic signal (typically 1 second) to the resolution programmable RTC counter. An interrupt is generated if SECIE=1 in the RTC_CRH register. It can be cleared only by software. Writing '1' has no effect.</p> <p>0: Second flag condition does not hold<br/>1: The second flag condition is established</p> |
|--|--|--|--|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

The functions of the RTC are controlled by this control register. When the peripheral is continuing the last write operation (RTOFF = 0), the RTC\_CRL register cannot be written.

Notes:

- Any flag bit will remain suspended until the appropriate RTC\_CR request bit is reset by the software, indicating that the requested interrupt has been received.
- All interrupts are disabled during reset, there are no pending interrupt requests, and the RTC register can be written
- When the APB1 clock is not running, the OWF, ALRF, SECF and RSF bits are not updated (cannot be synchronized).
- The OWF, ALRF, SECF and RSF bits can only be set by hardware and cleared by software.
- If ALRF = 1 and ALRIE = 1, an RTC global interrupt is allowed to be generated. If an EXTI line 17 interrupt is allowed to be generated in the EXTI controller, an RTC global interrupt and an RTC alarm interrupt are allowed to be generated.
- If ALRF = 1, an RTC alarm interrupt is allowed if the interrupt mode of the EXTI line 17 is set in the EXTI controller; If the event mode of EXTI line 17 is set in the EXTI controller, a pulse is generated on this line (no RTC alarm interrupt is generated).

### 27.4.3 RTC Prescale Load Register High Bit (RTC\_PRLH) (0x08)

The PRL register is used to hold the count value of the periodicity of the RTC prescaler. This register is write-protected by the RTOFF bit of the RTC\_CR register. Only when RTOFF = 1 is allowed to write the CPU.

This register is located in the VBAT field, and the data does not change after the microcontroller is powered down.

Address offset: 0x08

Reset value: 0x0000 0000

These bits are used to define the clock frequency of the counter according to the following formula:<br>$FTR\_CLK = f_{RTCCLK} / (PRL [19: 0] + 1)$ Note: The value of 0 is not recommended, otherwise RTC interrupt and flag bits cannot be generated correctly. |

#### 27.4.5 RTC Prescalation Remainder Register High Bit (RTC\_DIVH) (0x10)

This register is located in the VBAT field, and the data does not change after the microcontroller is powered down.

At each TR\_CLK cycle, the value of the RTC\_PRL register is reloaded into the RTC prescalation counter. The user can obtain an accurate time measurement by reading the RTC\_DIV register to obtain the current value of the prescalation counter without stopping the operation of the frequency division counter.

This register is a read-only property, and when there is any change in the value of the RTC\_PRL or RTC\_CNT register, the register value will be reloaded by the hardware.

#### 27.4.7 RTC Count Register High (RTC\_CNTH) (0x18)

This register is located in the VBAT field, and the data does not change after the microcontroller is powered down.

The RTC module has a 32-bit programmable counter, which is accessed through two registers. The count is based on the TR\_CLK time reference generated by the prescaler.

RTC\_CNT register is used to store the count value of the counter. The register is write-protected, and the CPU can only write when RTOFF = 1. Write to the upper 16-bit RTC\_CNTH or lower 16-bit RTC\_CNTL register, load it directly into the corresponding programmable counter, and reload the RTC prescaler. When reading, the current value in the counter (system date) is returned.

Address offset: 0x18

Reset value: 0x0000 0000

#### 27.4.9 RTC alarm register high (RTC\_ALRH) (0x20)

This register is located in the VBAT field, and the data does not change after the microcontroller is powered down.

When the programmable counter (count) reaches the 32-bit value stored in the RTC\_ALR register, an alarm interrupt request is generated. This register is write-protected by the RTOFF bit, and a write operation is allowed if the RTOFF value is '1'.

Address offset: 0x20

Reset value: 0x0000 FFFF

## 28. Independent watchdog (IWDG)

### 28.1 Introduction

Independent watchdog register (IWDG for short), which has the characteristics of high security level, accurate timing and flexible use. IWDG can be used to detect and resolve faults caused by software errors and trigger a system reset when the counter reaches a specified TIMEOUT value (TIMEOUT). The Independent Watchdog (IWDG) is driven by a dedicated low-speed internal clock (LSI), which is still active even if the master clock fails.

The IWDG is best suited for applications that require the watchdog to run as a totally independent process outside the main application, but have lower timing accuracy constraints.

### 28.2 Main features

- ◆ Free running decrementing counter
- ◆ The clock is provided by an independent RC oscillator (can operate in stop mode and standby mode)
- ◆ When the watchdog is activated, a reset is generated when the counter is decremented to 0x000
- ◆ With low power freezing function, it can keep working state in stop mode and standby mode, and the counter keeps decrementing count

### 28.3 Function description

#### 28.3.1 CAN block diagram

Figure 28-1 IWDG module block diagram

Note: The watchdog function is in the Vcc power supply zone, that is, it can still work normally in shutdown and standby modes.

Write 0xCCCC in the key register (IWDG\_KR) to start enabling the independent watchdog; At this point the counter starts to count down from its reset value of 0xFFFF. When the counter counts to the end of 0x000, a reset signal (IWDG\_RESET) is generated.

Whenever 0xAAAA is written to the key register IWDG\_KR, the value in IWDG\_RLR is reloaded into the counter to avoid an IWDG reset.

Table 28-1 Watchdog Timeout 40 kHz Input Clock (LSI)

| Prescaler division ratios | PR [2: 0] bit | Minimum Time (ms)<br>PR [11: 0] = 0x000 | Maximum time (ms)<br>PR [11: 0] = 0xFFF |
|---------------------------|---------------|-----------------------------------------|-----------------------------------------|
| /4                        | 0             | 0.1                                     | 409.6                                   |
| /8                        | 1             | 0.2                                     | 819.2                                   |
| /16                       | 2             | 0.4                                     | 1638.4                                  |
| /32                       | 3             | 0.8                                     | 3276.8                                  |
| /64                       | 4             | 1.6                                     | 6553.6                                  |
| /128                      | 5             | 3.2                                     | 13107.2                                 |
| /256                      | 6             | 6.4                                     | 26214.4                                 |

Note: These times are given as per the 40 kHz clock. In fact, the RC frequency inside the microcontroller will vary between 30 kHz and 60 kHz. Furthermore, even if the frequency of the RC oscillator is accurate, the exact timing still depends on the phase difference between the APB interface clock and the RC oscillator clock, so there will always be a complete RC cycle that is uncertain. A relatively accurate watchdog timeout can be obtained by calibrating the LSI.

### 28.3.2 Hardware watchdog

If the user enables the "hardware watchdog" function in the selection byte, the watchdog will automatically start running after the system is powered on and reset; If the software does not write the corresponding value to the key register before the counter count ends, the system will generate a reset

### 28.3.3 Register access protection

Write access to the IWDG\_PR and IWDG\_RLR registers is protected. To modify the values of these two registers, IWDG\_KR must first be written to 0x5555. Writes to other numbers of these registers will re-turn write protection, such as write 0xAAAA, and IWDG\_PR and IWDG\_RLR will be re-protected. IWDG\_SR indicates whether the value of IWDG\_PR or IWDG\_RLR is being updated.

### 28.3.4 Debug mode

If the CPU enters debug mode, the counter of IWDG continues to work or stops depending on the status of the DBG\_IWDG\_STOP configuration bit in the DBG module in the debug module

### 28.3.5 Low power freeze

Depending on the IWDG\_STOP and IWDG\_STBY bits in the option byte, it is determined whether the counting is continued in the IWDG stop mode or standby mode. If the IWDG remains operating in stop or standby mode, the IWDG can wake up the microcontroller from the current low power mode.

## 28.4 TIMx registers

You can only operate the following registers in a word manner.

### 28.4.1 Key Value Register (IWDG\_KR)

Address offset: 0x00

Reset value: 0x0000 0000 (reset by standby mode)

| 0     | PVU      | R   | 0           | Watchdog prescaler value update<br>This bit is set to 1 by the hardware, indicating that the prescaler value is being updated. It is reset by hardware when the prescaler update operation is completed.      |

Note: Before updating IWDG\_PR and IWDG\_SR.RLR, wait for IWDG\_PVU and IWDG\_SR.RVU to be 0, respectively. However, after updating IWDG\_PR and IWDG\_RLR, you do not have to wait for IWDG\_SR.PVU and IWDG\_SR.RVU to be 0, and you can continue to execute subsequent code.

## 29. Window watchdog (WWDG)

### 29.1 Introduction

Window watchdogs are usually used to monitor software failures caused by application running away caused by external interference or unforeseen logical conditions. Unless the value of the decrement counter is refreshed before the T [6] bit becomes 0, the watchdog circuit generates a reset when the preset time period is reached. If the 7-bit decrement counter value (in the control register) is refreshed before the decrement counter reaches the window register value, then a reset will also occur. This indicates that the decrement counter needs to be refreshed in a limited time window.

### 29.2 Main features

- Programmable free-running downcounter
- If the watchdog is activated, a system reset occurs when any of the following conditions are met:
  - The decrement counter has a value less than 0x40
  - The decrement counter is reloaded outside the window
- If the watchdog is activated and the early wake-up interrupt (EWI) is turned on, the EWI is generated when the decrement counter is equal to 0x40, and the software may reload the counter within the EWI interrupt program to avoid WWDG reset.

Figure 29-1 WWDG module block diagram

### 29.3 WWDG functional description

If the watchdog is enabled (the WDGA bit in the WWDG\_CR register is set to "1"), and when the 7-bit (T [6: 0]) decrement counter is flipped from 0x40 to 0x3F (T [6] bit cleared), a reset is generated. If the software reloads the counter when the counter value is greater than the value in the window register, a reset will be generated.

The software must be written to the WWDG\_CR register periodically during normal operation to prevent the microcontroller from resetting. A write operation can only be performed if the counter value is less than the value of the window register. The value stored in the WWDG\_CR register must be between 0xFF and 0xC0:

#### ■ Enabling the watchdog

When WWDG\_SW in the option byte selects the software to start WWDG (WWDG\_SW = 1), WWDG is turned off after the system is reset, and WWDG is enabled by setting WDGA in WWDG\_CR to 1. Once WWDG is started by the software, it cannot be shut down unless a system reset occurs.

When WWDG\_SW in the option byte selects hardware start WWDG (WWDG\_SW = 0), the WWDG clock starts automatically after the system is reset, and WWDG is in the ON state and cannot be turned off.

#### ■ Controlling the downcounter

This downcounter is free-running, counting down even if the watchdog is disabled. When the watchdog is enabled, the T [6] bit must be set to 1 to prevent a reset from occurring immediately.

The T[5:0] bits contain the number of increments which represents the time delay before the watchdog produces a reset. The timing varies between a minimum and a maximum value due to the unknown status of the prescaler when writing to the WWDG\_CR register.

The configuration register (WWDG\_CFR) contains the upper limit value of the window: to avoid a reset, the decrement counter must be reloaded when its value is less than the value of the window register and greater than 0x3F.

Another way to reload the counter is to utilize an early wake-up interrupt (EWI). Setting the EWI bit in the WWDG\_CFR register turns on the interrupt. This interrupt is generated when the decrement counter reaches 0x40, and the corresponding interrupt service routine (ISR) can be used to load the counter to prevent the WWDG from resetting. This interrupt can be cleared by writing '0' in the WWDG\_SR register.

Note: You can use the T [6] bit to generate a software reset (set the WDGA bit to "1" and the T [6] bit to "0").

## 29.4 How to program the watchdog timeout

You can calculate the timeout of the window watchdog using the formula provided in the figure below.

Warning: When writing to the WWDG\_CR register, always set the T [6] bit to '1' to avoid immediately generating a reset.

Figure 29-2 Window Watchdog Timing Diagram

The formula for calculating the WWDG timeout value is as follows:

$$tWWDG = tPCLK \times 4096 \times 2WWDGTB [1: 0] \times (T [5: 0] + 1) \text{ (ms)}$$

## 29.5 Debug mode

When the microcontroller enters the debug mode (Cortex-M4F core stops), it is determined whether the counter of WWDG continues to work or stops according to the state of the DBG\_WWDG\_STOP configuration bit in the debug module. See the Debug support for details.

## 30. External serial memory controller (ESMC)

### 30.1 Introduction

ESMC (External serial memory controller) is a dedicated communication interface for single, dual, quad, dual-quad and octal channels SPI interface memory (NOR Flash, PSRAM, etc.). It can run in either of the following two modes:

- Indirect mode: All operations are performed using ESMC registers
- Memory mapped (XIP) mode: External flash memory is mapped to the device address space and the system treats it as internal memory

Using dual memory mode, two Quad SPI memories are accessed simultaneously, similar to a single Octal SPI memory, doubling throughput and capacity.

### 30.2 Main Features

- Supports two functional modes: indirect and memory mapped
- Can transmit/receive 8 bits simultaneously
  - Dual flash mode, which allows simultaneous transmission/reception of 8 bits by accessing two flashes in parallel
  - Octal SPI
- Supports SDR and DDR
- Has receive and transmit FIFO
- Allows 8-bit, 16-bit, and 32-bit data access (indirect mode only supports 32-bit read)
- In indirect mode, DMA operation is supported
- Interrupt indicating FIFO status and completion of operation

### 30.3 ESMC functional description

#### 30.3.1 ESMC external memory connection diagram

Figure 30-1 ESMC connection diagram (when Dual QSPI Memory mode is disabled)

Figure 30-2 ESMC connection diagram (when Dual QSPI Memory mode is set)

Figure 30-3 ESMC connection diagram (when OSPI Memory mode is set)

### 30.3.2 ESMC Command Sequence

The ESMC uses commands to communicate with external memory. Each command can include 5 stages: Instruction, Address, Spare Byte, Dummy, Data. Any configuration of these phases can be skipped, but at least one of the instruction, address, spare byte, or data phases must be present.

The nCS pulls low before the start of each command and pulls high again after the completion of each command.

Figure 30-4 QSPI instruction example

### Instruction phase

At this stage, an 8-bit instruction configured in the instruction field of the ESMC\_SFCCR [7: 0] or ESMC\_ADDR24 [7: 0] register is sent to the flash memory, specifying the type of operation to be performed.

Although most flash memories can only receive one bit of instruction at a time (per cycle) from the IO pin (single SPI mode), the instruction stage can choose to send 2 bits at a time (IO0/IO1 in dual SPI mode), 4 bits at a time (IO0/IO1/IO2/IO3 in quad SPI mode), or 8 bits at a time (IO0/IO1/IO2/IO3/IO4/IO5/IO6/IO7 in eight SPI mode).

The length of the instruction may be set to no instruction length, 1 byte instruction and 2 byte instruction.

The size of the instruction length is implemented by the following registers:

| Size of instruction length | Configured registers                                                                                                                                                                             |
|----------------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| No instruction code        | Enable bit: ESMC_DCR/ESMC_XDCR/ESMC_XDCR_WE.NO_CMD = 1                                                                                                                                           |
| 1-byte instruction code    | Enable bit: none, bit 1 byte instruction by default<br>1st byte instruction: ESMC_ADDR24.INS1 [7: 0] or ESMC_SFCCR (send instruction only)                                                       |
| 2-byte instruction code    | Enable bit: ESMC_CR3/ESMC_XCR3/ESMC_XCR3_WE.CMD_EXT = 1<br>1st byte instruction: ESMC_ADDR24.INS1 [7: 0]<br>2byte instruction: write bit ESMC_ADDR32. MREG [7: 0] or ESMC_XMODE or ESMC_XMODE_WE |

### Address phase

In the address phase, 1-4 bytes are sent to the flash memory to indicate the address of the operation. The number of address bytes to be sent is configured in the 32 BIT\_ADDR, 16 BIT\_ADDR, 8 BIT\_ADDR bits of the ESMC\_CR3 register (the default is a 24-bit address). In indirect mode, the address byte to be sent is specified in the address [31: 0] field of the ESMC\_ADDR register, while in memory-mapped mode, the address is given directly over the AHB bus.

Addresses can be sent 1 bit at a time (through IO0 in single SPI mode), 2 bits at a time (through IO0/IO1 in dual SPI mode), 4 bits at a time (through IO0/IO1/IO2/IO3 in quad SPI mode) or 8 bits at a time (IO0/IO1/IO2/IO3/IO4/IO5/IO6/IO7 in eight SPI mode).

When the ESMC\_SOCR register NO\_ADDR bit is set, the address phase will be skipped and the command sequence will proceed directly to the next phase.

The ESMC contains four 8-bit address registers ADDR3, ADDR2, ADDR1, ADDR0, allowing addressing flash memory that supports 24-bit and 32-bit address fields. By default, ESMC is configured as a 24-bit address.

A 32-bit address is sent from the ESMC during access to the external SPI flash memory. By default, only the 24 LSB bits of the address register are sent. When ADDR32BIT (CR3 [2]) is set, the 32-bit address will be transferred out of the ESMC. The address register values are transmitted in the currently selected SPI mode (extended SPI, single SPI, dual SPI, quad SPI, or eight SPI) channel. The address register should be written before the ESMC loads the SFCR register.

#### **Alternate byte phase**

In the spare byte phase, 1 byte is sent to the flash memory and is typically used to control the mode of operation. The spare byte data to be transmitted is configured in the MREG [7: 0] field of the ESMC\_ADDR32 [23:16] register.

The spare byte stage can send 2 bits at a time (through IO0/IO1 in dual SPI mode), or 4 bits at a time (through IO0/IO1/IO2/IO3 in quad SPI mode).

When ESMC\_SOCR.SEND\_M = 0, the spare byte phase will be skipped and the command sequence will proceed directly to the next phase.

#### **Dummy stage**

In the DUMMY phase, 1-63 cycles are given without sending or receiving any data, so that the flash memory has time to prepare data when using a higher clock frequency. The number of cycles given by this phase is specified in the DUMMY [5: 0] field of the ESMC\_DCR register. In both SDR and DDR modes, the duration is specified as the number of full SCLK cycles.

When DUMMY is zero, the DUMMY cycle phase is skipped and the command sequence goes directly to the data phase.

#### **Data Phase**

In the data phase, any number of bytes may be sent to or received from the flash memory.

In indirect mode, the number of bytes transmitted/received is specified in the ESMC\_BCR register.

In the indirect write mode, data sent to the flash memory must first be written to the ESMC\_DATA register, while in the indirect read mode, data received from the flash memory is obtained by reading the ESMC\_DATA register.

In memory-mapped mode, the data read/written is directly through the AHB bus.

The data phase can send/receive 1 bit (through IO0/IO1 in single SPI mode), 2 bits (through IO0/IO1 in dual SPI mode), 4 bits (through IO0/IO1/IO2/IO3 in quad SPI mode) or eight bits (IO0/IO1/IO2/IO3/IO4/IO5/IO6/IO7 in eight SPI mode) at a time.

### **30.3.3 ESMC Interface Protocol Mode**

#### **Single SPI mode**

Legacy SPI mode allows only a single bit to be transmitted/received serially. In this mode, data is sent to the flash memory via the SO pin (this I/O is shared with IO0) and received from the flash memory via the SI pin (this I/O is shared with IO1).

Single SPI mode is used by setting ESMC\_SOCR [1: 0] to 00.

#### **Dual SPI mode**

In dual SPI mode, two bits of data are transmitted/received simultaneously via the IO0/IO1 pin.

The dual SPI mode is used by setting ESMC\_SOCR [1: 0] to 01.

#### **Quad SPI Mode**

In Quad SPI mode, four bits of data are sent/received simultaneously through the IO0/IO1/IO2/IO3 pins.

The quad SPI mode is used by setting ESMC\_SOCR [1: 0] to 10.

#### **Dual Flash mode**

When 2QUAD bit (ESMC\_CR) is 1 and ESMC\_SOCR [1: 0] is set to 11, ESMC is in dual flash mode where two external QUAD SPI flashes (Flash1 and Flash 2) are used to send/receive 8 bits of data per cycle (or 16 bits of data in DDR mode), doubling throughput and capacity.

Each flash uses the same SCLK pin and optionally the same nCS pin, but each has separate IO0, IO1, IO2, and IO3 pins.

The dual flash mode can be combined with the SDR or DDR mode.

Each byte of [7: 4] bits of data is stored in flash memory 1, and each byte of [3: 0] bits of data is stored in flash memory 2.

When reading a Flash status register in dual Flash mode, twice as many bytes should be read compared to reading the same byte in single Flash mode. This means that if the status bit of each Flash is 8 bits, QUAD SPI must be configured to be 2 bytes, and QUADSPI receives one byte from each Flash. If the state of each Flash is 16 bits, QUAD SPI must be configured to be 4 bytes, and QUADSPI receives two bytes from each Flash.

The first byte of the data register is the first byte of Flash1, and the second byte is the first byte of Flash2. Then, the third byte of the data register is the Flash1 second byte, and the fourth byte is the Flash2 second byte (in the case of Flash having a 16-bit status register).

In dual flash mode, an even number of bytes must always be accessed. Therefore, ESMC\_BCR needs to be set to an even number.

Note: In dual flash mode, the address written to the external memory is half of the actual address. For example, the written address is 0x8, and the actual address sent to the external memory is 0x4. The read address is consistent with the actual address. For example, the read address is 0x8, and the actual address sent to the external memory is also 0x8.

#### **Octal SPI Mode**

In eight SPI mode, eight bits of data are sent/received simultaneously through the IO0/IO1/IO2/IO3/IO4/IO5/IO6/IO7 pins.

The eightSPI mode is used by setting ESMC\_SOCR [1: 0] to 11.

### SDR mode

By default, the DDRDATA, DDRADDR, DDRCMD bits (ESMC\_SOCR) are 0, and ESMC operates in single data rate (SDR) mode.

In SDR mode, when ESMC drives the IO0, IO1, IO2, IO3 pins, these pins only transition with the SCLK falling edge.

When receiving data in SDR mode, it is assumed that the flash memory transmits data using the falling edge of the SCLK, and the ESMC samples the signal using the upper and falling edge of the SCLK.

### DDR mode

When the DDR bit is set (data, address, instruction can be set respectively by setting the DDRDATA, DDRADDR, DDRCMD bits of the ESMC\_SOCR register), the ESMC operates in dual data rate (DDR) mode.

In DDR mode, when the ESMC drives the IO0, IO1, IO2, IO3, IO4, IO5, IO6, IO7 pins in the address/spare byte/data phase, one bit of data is sent on each falling and rising edge of the SCLK.

When receiving data in DDR mode, assuming that the flash memory also transmits data using rising and falling SCLK edges, the ESMC samples the signal after half of the SCLK period (at the next opposite edge).

### Usage of DQS (/RWDS)

The DQS pin can be used to read data strobe.

In eight SPI mode, the XSPI\_RWDS enable of the configuration register (ESMC\_CR3) is set to 1 to enable DQS management.

Figure 30-5 8-DDR read timing of DQS in line mode

Table 30-1 The memory types that ESMC can support are as follows

| Device Type | Interface protocol mode |     | Data direction |
|-------------|-------------------------|-----|----------------|
| NOR Flash   | 1 line                  | SDR | Reception      |
|             |                         | DDR | Transmission   |
|             | 2 lines                 | SDR | Reception      |
|             |                         | DDR | Transmission   |
|             | 4 lines                 | SDR | Reception      |
|             |                         | SDR | Reception      |

|       |               |     |              |
|-------|---------------|-----|--------------|
|       |               |     | Transmission |
|       |               | DDR | Reception    |
|       | Double 4 wire | SDR | Reception    |
|       |               | DDR | Reception    |
|       | 8 line        | SDR | Transmission |
|       |               | DDR | Reception    |
| PSRAM | 1 line        | SDR | Reception    |
|       |               |     | Transmission |
|       | 4 lines       | SDR | Reception    |
|       |               |     | Transmission |
|       | Double 4 wire | SDR | Reception    |
|       |               |     | Transmission |

### 30.3.4 ESMC Working Mode

ESMC has two modes of operation:

- Indirect mode (register control)
- Memory Mapping Mode

The working mode is set by the XIP\_EN bit (6th bit of ESMC\_CR) (this module supports XIP read and XIP write functions, but the XIP write function only supports PSRAM use except 8 lines):

When set to 1, it is memory mapped mode.

When set to 0, it is indirect mode.

#### 30.3.4.1 ESMC indirect mode

In indirect mode, commands are initiated by writing to the relevant register and data is transferred by writing or reading the data register.

When REC = 0 (7th bit of ESMC\_DCR), ESMC is in indirect write mode, sending bytes to Flash during the data phase by writing to the data register (ESMC\_DATA).

When REC = 1, ESMC is in indirect read mode, receiving bytes from Flash during the data phase by reading ESMC\_DATA.

#### 30.3.4.2 ESMC memory mapping mode

In memory mapped mode, ESMC allows data to be read or written directly from SPI Flash. In this mode, the ESMC operates as a serial-to-parallel converter between the SPI flash and the CPU. Different from indirect mode, memory mapping (XIP) mode has dedicated registers, and the general registers are XSTRR, XSSOCR and XSSOCR\_WE; Read operations include XMODE, XSFCR, XSOCR, XDCCR and XCR3; The write operation registers are XMODE\_WE, XSFCR\_WE, XSOCR\_WE, XDCCR\_WE, and XCR3\_WE.

The instructions sent during the XIP access are stored in the ESMC XIP instruction registers (XSFCR and XSFCR\_WE). These two registers function similarly to the SFCR registers, but are only used in XIP mode, and writing to the registers does not initiate instruction code transfer. The transfer of instructions is completed in the selected SPI mode.

To operate in XIP mode, you need to configure SPI Flash first. Once configured correctly, the XIP operation of the ESMC is ready after powering on and no further action is required.

The ESMC controller allows FLASH reads using the preset READ Command after the system is reset. Other transmission configurations need to be implemented by configuring XIP related registers through software.

In the XIP mode, the CPU starts the read operation according to the command of the XSFCR configuration of the ESMC or starts the transmission operation according to the command of the XSFCR\_WE configuration of the ESMC through the AHB bus, and the address comes from the AHB bus. In the process of using XIP, if the user wants to send a new FLASH command, he does not need to prohibit XIP, but only avoid any access to the XIP memory space during the operation, otherwise the operation will terminate and start XIP reading.

To disable XIP mode in ESMC, the XIP\_EN bit (ESMC\_CR[6]) needs to be cleared in the software. Once this bit is 0, access to the XIP bus has no effect on the ESMC. XIP operations are enabled by default, so READ can be started immediately after system reset. It can be disabled in the software by clearing the XIP enable bit (ESMC\_CR [6]). If the XIP\_EN bit (ESMC\_CR [6]) is cleared, the XIP bus is set to busy to indicate an access error.

Note: When XIP is written in mode0, it needs to be set to more than two-division frequency to work.

### 30.3.5 Programmable options for ESMC

#### 30.3.5.1 Byte count

ESMC uses a 32-bit register (BCR register) to control the transfer of data, including read operations and write operations;

ESMC supports fixed length data transfer, and by default ESMC will read/write data from external memory as long as there is at least one free space/at least one data in RXFIFO/TXFIFO. Once the storage space of the RXFIFO/TXFIFO is full/empty, the ESMC will enter the WAIT state and WAIT for the host to read data from the RXFIFO/TXFIFO or write data. The RXFIFO must be completely empty, or the TXFIFO must be written to full, before the next transmission can be started.

This mode is only available in indirect mode. After reading the specified number of bytes, the SSO pin is deactivated and the ESMC enters the IDLE state, waiting for the next command to be executed.

Table 30-2 The number of read and write bytes that can be supported in different modes

| Size      | Indirect mode read-ing | Indirect mode write | XIP Mode Read | XIP Mode Write | DMA Mode Read | DMA Mode Write |
|-----------|------------------------|---------------------|---------------|----------------|---------------|----------------|
| Bytes     | x                      | √                   | √             | √              | x             | √              |
| Half word | x                      | √                   | √             | √              | x             | √              |
| Word      | √                      | √                   | √             | √              | √             | √              |

#### 30.3.5.2 Polarity and Phase

ESMC only supports SPI protocol operation in Mode 0 and Mode 3.

This is achieved by configuring the ESMC\_CR2 [1: 0] register.

When ESMC\_CR2. CPOL and ESMC\_CR2. CPHA are both set to 0, mode 0 is indicated. If both ESMC\_CR2. CPOL and ESMC\_CR2. CPHA are set to 1, it is indicated as SPI mode 3.

Figure 30-6 Timing of Mode 0 and Mode 3 in SDR mode

Figure 30-7 Timing of Mode 0 and Mode 3 in DDR Mode

### 30.3.5.3 Baud rate

The BAUD rate register BAUD (0x3) is used to define the SCLK frequency of the ESMC, divided based on the system clock. When BAUD is set to 0x0 and 0x1, the frequency is divided into two; That is, the fastest SCLK clock is the two-division frequency of the system clock. Other values are calculated as:

$$\text{SCLK} = \text{HCLK} / \text{BAUD};$$

### 30.3.5.4 Timing control

The timing control register TCR (0x2) is used to define and control timing:

- Set the SETUP time of the nCS pin output before the transmission starts.
- Set the HOLD time of the nCS pin output after the end of transmission.
- Set the HIGH time of the Ncs pin output between successive commands.

Where the SETUP and HOLD times are configured in the ESMC\_TCR.HOLD [3: 0] register and the HIGH time is configured in the ESMC\_TCR.HIGH [3: 0] register. The time of SETUP and HOLD is the number of cycles in which the corresponding HCLK is inserted in units of HCLK. The time of HIGH is measured in units of SCLK, and the set value indicates the number of SCL cycles that the nCS pin needs to be held when it is HIGH.

Note: If the HIGH level time of the nCS pin exceeds the set HIGH time number, no new instructions are written and the nCS pin will not be pulled down.

### 30.3.5.5 ESMC command sending

By default, commands are sent in SINGLE mode at the beginning of each sequence. ESMC can also send specific commands in DUAL, QUAD, or OCTAL mode.

The ESMC has two command registers SFCR0 and SFCR1. The differences in the use of commands are as follows:

1. SFCR0 is used for single byte Flash command transmission, such as: RESET ENABLE (66h), RESET MEMORY (99h), etc. Write the command into the SFCR0 register, the command will be issued according to the current SPI mode setting, and once the command transfer is complete, the nCS pin will become inactive in order to execute the next command.
2. SFCR1 is used for non-single-byte Flash command transmission (including sequences such as ADDRESS/M [7: 0]/DUMMY/DATA).

### 30.3.5.6 ESMC command sequence configuration

A specific ESMC sequence can be transmitted by configuring the ESMC\_SOCR register. The following figure shows several Flash read/write operations supported by ESMC and their formats. As described below, configuring the control registers allows any combination of flash commands, including multi-SPI commands, addresses and data, SDR/DDR, and any number of DUMMY cycles.

Figure 30-8 single line SPI read command: MULTI ADDR = 0; MULTI COMM = 0; SPI\_MODE = 2 'b00;  
DUMMY! = 0

Figure 30-9 Two-line SPI read command: MULTI ADDR = 0; MULTI COMM = 0; SPI\_MODE = 2 'b01;  
DUMMY! = 0

Figure 30-10 2 IO readcommand: MULTI COMM = 0; MULTI ADDR = 1; SPI\_MODE = 2'b01; DUMMY! = 0

Figure 30-11 4-wire readcommand: MULTI ADDR = 0; MULTI COMM = 0; SPI\_MODE = 2'b10

Figure 30-12 4 IO read command: MULTI COMM = 0; MULTI ADDR = 1; SPI\_MODE = 2'b10

Figure 30-13 4 IO QPI mode read command: MULTI COMM = 1; MULTI ADDR = 1; SPI\_MODE = 2 'b10

The difference between 8-line mode and DDR mode and the above is transmission on more IO lines and double edge sampling. Other sequence contents are similar to the above commands.

### 30.3.5.7 Dummy Cycle Control

Set the number of Dummy cycles (bits [5: 0]) by ESMC\_DCR.Dummy[5: 0], and the maximum value allowed to set is 63. During the transmit Dummy cycle, the IO pin is set to a high impedance state and no data is stored in the RX FIFO or read out.

The REC bit (7th bit of the DCR) is used to specify the type of operation. When REC = 1, ESMC performs a read operation on FLASH. When REC = 0, ESMC writes to FLASH. If the DATA has been received (or sent), the ESMC enters the WAIT state and waits for the DATA to be read or written from the FIFO.

NO\_CMD (6th bit of DCR) is used to enable/disable sending instruction bytes to SPI Flash, and NO\_ADDR (5th bit of CR3) is used to enable/disable sending addresses. When the NO\_CMD bit is set, the ESMC sends only the address and the set Dummy cycle, and then sends the data bytes.

In addition, the value of the Dummy cycle setting is also related to the XSPI\_DUAL\_LAT\_OFF bit (the 7th bit of CR2). When XSPI\_DUAL\_LAT\_OFF = 1, the ESMC turns off double delay. When double delay is enabled when XSPI\_DUAL\_LAT\_OFF = 0. This feature is only available in xSPI (setting CR3[4] = 1, SOCR[1: 0] = 2 'h3, SOCR[7] = 1) mode.

Table 30-3 Number of DUMMY cycles in different modes

| DCR [5: 0] | DUMMY Cycles              |                                                                                  |                                                                                                    |
|------------|---------------------------|----------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------|

### 30.3.5.8 Slave selection output control

The SSOCR control register can be read or written to at any time, and it is used to select which slave to drive during transfer. The contents of the SSOCR register are automatically assigned to SS50-SS00. This register allows SPI operations with up to 6 different SPI flash memories.

### 30.3.5.9 Size of FIFO

ESMC has 3 FIFOs: TXFIFO for sending data in indirect mode, RXFIFO for receiving data in indirect mode, and XIPFIFO for receiving data in XIP mode. The depths are 16 bytes, 16 bytes, and 8 bytes respectively.

### 30.3.5.10 Sampling extension

Through the ESMC\_STR and ESMC\_XSTR registers, it is possible to configure the number of HCLKs that the sampling points of the data phase ESMC extend relative to the SCLK clock edge. By default, the value of these two registers is 0, and there is no delay between the sampling point and the SCLK. This feature is used with the following restrictions:

1. This function can only be used in SDR mode, not in DDR mode
2. The maximum value of the sample extension setting needs to be less than or equal to half of the SCLK period. For example, when ESMC\_BAUD is set to 2, the maximum value of ESMC\_STR and ESMC\_XSTR registers can only be set to 0x1.

## 30.3.6 DMA mode

DMA transmission is possible by enabling DMA\_EN (ESMC\_CR [3]). When ESMC is enabled, the hardware automatically generates a DMA send request or a DMA receive request signal. Before DMA operation, the ESMC should be initialized and the corresponding registers should be configured. In DMA mode, the ESMC generates a DMA send/receive request signal indicating that the ESMC expects data transfer, which will start once the ESMC pulls the nCS pin low and transmits the instruction and address to SPI Flash.

ESMC supports DMA burst read function (DMA burst write function is not supported). ESMC needs to set ESMC\_IER [2] = 1 first. After setting, ESMC will only send DMA requests after RXFIFO is full.

In addition, ESMC needs to pay attention to the following points when using DMA mode:

1. In DMA mode, the DMA module needs to be configured before transmission can begin.
2. In DMA mode, DMA\_EN (ESMC\_CR [3]) must be configured to 1 before writing the instruction.
3. In DMA receiving mode, it can only accept word reading, but does not support byte and half-word reading. In DMA sending mode, byte, half-word, and word writing are supported.
4. DMA operations can only be operated in register mode (not in XIP mode).
5. In DMA burst read mode, the amount of data transferred must be configured to be an integer multiple of a single burst data.

### 30.3.7 ESMC interrupts

The ESMC has an interrupt enabling GIE (ESMC\_CR[4]) that enables/disables all interrupt sources in the ESMC.

The ESMC has four interrupt-related control registers ESMC\_IER1, ESMC\_IER2, ESMC\_IFR1, and ESMC\_IFR2. Several interrupt sources of ESMC have their own masking bits regardless of the global

IE bits. The IE mask bits all have corresponding flag bits. When a specific event occurs, the flag bit is automatically set regardless of whether the corresponding IE bit is set. If you want to generate an interrupt request, you must set both the global GIE (ESMC\_CR [4]) bit and the corresponding IE (ESMC\_IER1 and ESMC\_IER2) mask bits.

Interrupts can be generated in the following events:

| Interrupt Event   | Event Flag      | Enable Control Bit |
|-------------------|-----------------|--------------------|
| ADDR DONE         | ADDRDONEIF      | ADDRDONEIE         |
| RX FIFO Word      | RXFIFOWIF       | RXFIFOWIE          |
| DATA WAIT         | DATAWAITIF      | DATAWAITIE         |
| IDLE              | IDLE_DONEIF     | Idle_DONEIE        |
| RX FIFO FULL      | RXFIFFIF        | RXFIFFIE           |
| RX FIFO HALF FULL | RXFIFOHFIF      | RXFIFOHFIE         |
| FIFO not Empty    | RXFIFONEIF      | RXFIFONEIE         |
| COMMAND DONE      | COMMANDDONEIF   | COMMANDDONEIE      |
| RXTIMEOUT         | RXTOUTIF        | -                  |
| XIP WE Instr set  | XIPWEInstrsetIF | -                  |
| TX WORD OVER      | TXWORDOVIF      | TXWORDOVIE         |
| TX FIFO OVER      | TXFIFOOVIF      | TXFIFOOVIE         |
| TX FIFO full      | TXFIFFIF        | TXFIFFIE           |
| TX FIFO HALF FULL | TXFIFOHFIF      | TXFIFOHFIE         |
| TX FIFO Empty     | TXFIFOEIF       | TXFIFOEIE          |
| XIP Rd Instr Set  | XIPRDInstrSetIF | -                  |

Note: The following are the differences between registers with similar functions in ESMC\_SR and ESMC\_IFR1/2.

ESMC\_SR. Difference between IDLE\_STATE and ESMC\_IFR.IDLE\_DONE

The ESMC\_SR.IDLE\_STATE status register indicates that the ESMC's state machine has entered the IDLE state. While ESMC\_IFR.IDLE\_DONE represents an idle interrupt request, which refers to a transition from a non-idle state to an idle state. For example, at high frequency division, ESMC is idle. If a new command is written, ESMC\_IFR.IDLE\_DONE will immediately change from 1 to 0. ESMC\_SR.IDLE\_STATE needs to change from 1 to 0 after the nCS pin is pulled up (after ESMC is not idle).

When using ESMC\_SR.IDLE\_STATE at high frequency division, it is necessary to read the ESMC\_IFR.CMDIF flag bit first after sending the instruction, and then read the register after ESMC\_IFR.CMDIF is set.

ESMC\_IFR2.TXFIFOOV and ESMC\_SR.TXFIFOOV have the same function. ESMC\_IFR.DATAWAIT and ESMC\_SR.DATAWAIT has the same functionality.

The difference between these two sets of signals is: ESMC\_IFR.DATAWAIT and ESMC\_IFR2. ESMC\_IFR2.TXFIFOOV is an interrupt request signal, ESMC\_SR.DATAWAIT and ESMC\_SR.TXFIFOOV is a status bit signal.

## 30.4 ESMC register description (byte access only)

ESMC register base address: 0xA000 1000

|------|--------|-----|-------------|------------------------------------------------------------------------------|
| 7: 0 | RXTOUT | RW  | 8'h3F       | This register is used to set the time period of RX TIMEOUT (in SCLK cycles). |

## 30.5 XIP Mode Control Register-Read Operation

### 30.5.1 XIP SPI Flash Command Register (ESMC\_XSFCR)

Address offset: 0x20

Reset value: 0x0B

This register supports soft\_rst reset

| Register | ADDR | Bit7         | Bit6 | Bit5 | Bit4 | Bit3 | Bit2 | Bit1 | Bit0 | Reset |
|----------|------|--------------|------|------|------|------|------|------|------|-------|
| XSFCR    | 0x20 | XSFCR [7: 0] |      |      |      |      |      |      |      | 0x0B  |

| Bit  | Name        | R/W | Reset Value | Function                 |
|------|-------------|-----|-------------|--------------------------|
| 7: 0 | XINS [7: 0] | RW  | 8'hB        | Instructions in XIP mode |

### 30.5.2 XIP SPI output control register (ESMC\_XSOCR)

Address offset: 0x21

Reset value: 0x02

This register supports soft\_rst reset

| Register | ADDR | Bit7     | Bit6     | Bit5     | Bit4       | Bit3       | Bit2   | Bit1            | Bit0 | Reset |
|----------|------|----------|----------|----------|------------|------------|--------|-----------------|------|-------|
| XSOCR    | 0x21 | DDR DATA | DDR ADDR | DDR COMM | MULTI ADDR | MULTI COMM | Send_M | SPI_MODE [1: 0] |      | 0x02  |

| Bit | Name      | R/W | Reset Value | Function                                                                                                                                                  |
|-----|-----------|-----|-------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------|
| 7   | DDRDATA   | RW  | 0           | Dual data rate operation is enabled during data reception/transmission. When this bit is set, data is moved in/out on both SCLK clock edges.              |
| 6   | DDRADDR   | RW  | 0           | Dual data rate operation is enabled during flash address byte transmission. When this bit is set, the address shifts out on both SCLK clock edges.        |
| 5   | DDRCMD    | RW  | 0           | Dual data rate operation is enabled during flash instruction byte transmission. When this bit is set, the instruction moves out on both SCLK clock edges. |
| 4   | MULTIADDR | RW  | 0           | Enable multi-bit addresses<br>When this bit is set, the address bytes and data bytes are sent in the same format.                                         |

|      |                |    |      |                                                                                                                                                                                                                                                                                                        |
|------|----------------|----|------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|      |                |    |      | Where the address bits are sent in double, quadruple or octal format respectively, if MULTIADDR is clear, it means that the address is sent in single SPI mode.                                                                                                                                        |
| 3    | MULTICMD       | RW | 0    | Enable multi-bit instructions<br>When this bit is set, the instruction byte and the data byte are sent in the same format.<br>Where the instruction bits are sent in double, quad or octal format, respectively, and if MULTICMD is cleared, it means that the instruction is sent in single SPI mode. |
| 2    | SENM           | RW | 0    | An additional M [7: 0] is transmitted after ADDR (8-bit, 24-bit, or 32-bit).                                                                                                                                                                                                                           |
| 1: 0 | SPIMODE [1: 0] | RW | 2'h2 | Set the SPI transport format:<br>2'b00 SINGLE SPI<br>2'b01 DUAL SPI<br>2'b10 QUAD SPI<br>2'b11 OCTAL SPI                                                                                                                                                                                               |

### 30.5.3 XIPReadDummy Control Register (ESMC\_XDCR)

Address offset: 0x22

Reset value: 0x80

This register supports soft\_rst reset

| Register    | ADDR        | Bit7 | Bit6   | Bit5 | Bit4 | Bit3 | Bit2 | Bit1 | Bit0         | Reset |
|-------------|-------------|------|--------|------|------|------|------|------|--------------|-------|

## 30.6 XIP mode control general purpose register

### 30.6.1 XIP Mode Register (ESMC\_XMODE)

Address offset: 0x24

Reset value: 0x00

This register supports soft\_rst reset

| Register     | ADDR        | Bit7     | Bit6 | Bit5 | Bit4 | Bit3 | Bit2 | Bit1 | Bit0 | Reset |
|--------------|-------------|----------|------|------|------|------|------|------|------|-------|
| <b>XMODE</b> | <b>0x24</b> | M [7: 0] |      |      |      |      |      |      |      | 0x00  |

| Bit  | Name     | R/W | Reset Value | Function                                                                                                               |
|------|----------|-----|-------------|------------------------------------------------------------------------------------------------------------------------|
| 7: 0 | M [7: 0] | RW  | 8'h0        | The contents of the ESMC_XCR3 register are sent after the address byte only if the SEND_M bit is set in this register. |

### 30.6.2 XIP write mode register (ESMC\_XMODE\_WE)

Address offset: 0x25

Reset value: 0x00

This register supports soft\_rst reset

| Register        | ADDR        | Bit7     | Bit6 | Bit5 | Bit4 | Bit3 | Bit2 | Bit1 | Bit0 | Reset |
|-----------------|-------------|----------|------|------|------|------|------|------|------|-------|
| <b>XMODE_We</b> | <b>0x25</b> | M [7: 0] |      |      |      |      |      |      |      | 0x00  |

| Bit  | Name     | R/W | Reset Value | Function                                                                                                                  |
|------|----------|-----|-------------|---------------------------------------------------------------------------------------------------------------------------|
| 7: 0 | M [7: 0] | RW  | 8'h0        | The contents of the ESMC_XCR3_WE register are sent after the address byte only if the SEND_M bit is set in this register. |

### 30.6.3 XIP slave select output control register (ESMC\_XSSOCR)

Address offset: 0x26

Reset value: 0x01

This register supports soft\_rst reset

| Register      | ADDR        | Bit7 | Bit6      | Bit5      | Bit4 | Bit3 | Bit2 | Bit1 | Bit0 | Reset |

| 7    | Reserved     | -   | 0           | -                                                                                                                                                                                                                                                                                                                                              |
| 6    | NO_CMD       | RW  | 0           | When this bit is set, the instruction will be omitted and the transfer will begin with the address.                                                                                                                                                                                                                                            |
| 5: 0 | DUMMY [5: 0] | RW  | 6'h0        | Defines the number of DUMMY cycles generated after address transfer.<br>The setting of DUMMY CYCLE is also related to the setting of some registers (ESMC_XCR2_WE [7], ESMC_XSOCCR_WE [7], ESMC_XCR3_WE [5], ESMC_XSOCCR_WE [1: 0]). There will be three cases: non-xSPI mode, xSPI mode turns off double delay and xSPI enables double delay. |

### 30.7.4 XIP write configuration register 3 (ESMC\_XCR3\_WE)

Address offset: 0x2B

Reset value: 0x00

This register supports soft\_rst reset

| Register | ADDR | Bit7    | Bit6 | Bit5    | Bit4      | Bit3    | Bit2      | Bit1      | Bit0     | Reset |
|----------|------|---------|------|---------|-----------|---------|-----------|-----------|----------|-------|
| XCR3_WE  | 0x2B | No_DATA | Res  | CMD_Ext | XSPI_RWDS | NO_ADDR | ADDR32BIT | ADDR16BIT | ADDR8BIT | 0x00  |

| Bit | Name | R/W | Reset Value | Function |
|-----|------|-----|-------------|----------|
|-----|------|-----|-------------|----------|

|   |           |    |   |                                                                                                                                                                                    |
|---|-----------|----|---|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 7 | No_DATA   | RW | 0 | When the setting is enabled, the address will not enter the data wait state after sending.<br>This bit can be used to erase the command, sending only the instruction and address. |
| 6 | Res       |    | 0 |                                                                                                                                                                                    |
| 5 | CMD_Ext   | RW | 0 | When setting enabled, the ESMC sends extra bytes (contents of the M register) after sending the command.                                                                           |
| 4 | XSPI_RWDS | RW | 0 | Supports the xSPI mode RWDS pin when setting enabled.                                                                                                                              |
| 3 | NO_ADDR   | RW | 0 | When set to enable, ESMC does not send address bytes, instruction bytes followed by DUMMY cycles (if any) and data bytes.                                                          |
| 2 | ADDR32BIT | RW | 0 | Enable 32-bit addresses                                                                                                                                                            |
| 1 | ADDR16BIT | RW | 0 | Enable 16-bit addresses                                                                                                                                                            |
| 0 | ADDR8BIT  | RW | 0 | Enable 8-bit addresses                                                                                                                                                             |

## 30.8 ESMC Register Description

ESMC register base address: 0xA000 1000

### 30.8.1 24-bit address register (ESMC\_ADDR24)

Address offset: 0x08

Reset value: 0x0000000B

This register can only be accessed word-wise (32-bit)

| 31           | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23          | 22 | 21 | 20 | 19 | 18 | 17 | 16 |

|-------|--------------|-----|-------------|-----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 31: 8 | ADDR [23: 0] | RW  | 24'h0       | 24-bit address<br>Use a 24-bit address when ESMC_CR3 [2] = 0 (default 24-bit address mode)<br>The address register values are transmitted in the currently selected SPI mode (extended SPI, single SPI, dual SPI, quad SPI, or eight SPI) channel. The address register should be written before the ESMC loads the ESMC_SFCR register. |
| 7: 0  | SFCR [7: 0]  | RW  | 8'h0B       | SPI instruction settings                                                                                                                                                                                                                                                                                                                |

### 30.8.2 32-bit address register (ESMC\_ADDR32)

Address offset: 0x0C

Reset value: 0x0001 0000

This register can only be accessed word-wise (32-bit)

SS0 ~ 1 is used to configure which slave select output should be driven during the SPI master transfer. The contents of the registers are automatically assigned to SS10-SS00. This register allows easy SPI operation with up to 2 different SPI flash memories.

| Bit   | Name        | R/W | Reset Value | Function                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
|-------|-------------|-----|-------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 31: 0 | BCR [31: 0] | RW  | 32'h0       | Number of data read and written<br>ESMC supports fixed-length data transfer, and by default ESMC will read/write data from external memory as long as the RXFIFO/TXFIFO has at least one free space/at least one data. Once the storage space of the RXFIFO/TXFIFO is full/empty, the ESMC will enter the WAIT state and WAIT for the host to read data from the RXFIFO/TXFIFO or write data. The RXFIFO must be completely empty or new data must be written to the TXFIFO before the next transfer can be resumed. After the ESMC reads the specified number of bytes, the nCS pin is deactivated and the ESMC goes idle, waiting for the next command to be executed. This register allows user commands to receive 232-1 bytes of data. |

## 31. SDIO Interface (SDIO)

### 31.1 Introduction

The SD/SDIO MMC card host module provides an operation interface between the AHB peripheral bus and the multimedia card (MMC), the SD memory card, the SDIO card and the CE-ATA device.

The MMC system specification sheet is published by the MMCA Technical Committee and is available on the Multimedia Card Association's website.

CE-ATA System Specifications are available on the CE-ATA Working Group's website.

The SDIO features include the following:

- Full compliance with SD Memory Card Specifications Version 2.0
- Full compliance with SD I/O Card Specification Version 2.0
- Full compliance with MultiMediaCard System Specification Version 4.2
- Fully compliance with the CE-ATA digital protocol Rev1.1
- Supports sending commands and requesting interrupts from the host processor

Notes:

SDIO does not support communication mode of SPI mode

It only supports the I/O part of SD card or composite card in I/O mode, and does not support all required commands in SD storage devices. There are some commands here that do not work in the SD I/O card, such as the erase command, so they are not supported by SDIO. In addition, several commands are different between SD memory cards and SD I/O cards and thus are not supported in the SDIO.

SDIO consists of 2 parts:

- SDIO adapter module: realizes all related functions of MMC/SD/SD I/O card, such as clock generation, command and data transmission.
- AHB bus interface: operates the registers in the SDIO adapter module and generates interrupt and DMA request signals.

Figure 31-1 SDIO block diagram

SDIO\_D [0] is used for data transfer by default after reset. After initialization, the host can change the width of the data bus. If an MMC is connected to the bus, SDIO\_D [0], SDIO\_D [3: 0], or SDIO\_D [7: 0] may be used for data transmission.

If an SD or SD I/O card is connected to the bus, SDIO\_D [0] or SDIO\_D [3: 0] can be used for data transmission through the host configuration. All data lines operate in push-pull mode.

SDIO\_CMD has two modes of operation:

- Open mode for initialization (only for MMC version V3.31 or earlier)
- Push-pull mode for command transmission (SD/SD I/O cards and MMC V4.2 also use push-pull drive at initialization).

The following table applies to the MMC/SD/SD I/O card bus:

Table 31-1 SDIO Pin Definition

| Pin           | Direction     | Description                                                                     |
|---------------|---------------|---------------------------------------------------------------------------------|
| SDIO_CLK      | Output        | MMC/SD/SDIO card clock. This is the clock line from the host to the card        |
| SDIO_CMD      | bidirectional | MMC/SD/SDIO card commands. This is a bidirectional command/response signal line |
| SDIO_D [7: 0] | bidirectional | MMC/SD/SDIO card data. These are bidirectional data buses.                      |

## 31.2 SDIO adapter

The SDIO adapter includes a control unit, a command unit, and a data unit that can generate signals to the card. A specific description of these signals is as follows:

SDIO\_CLK: The clock supplied to the card by the SDIO controller. Each clock cycle sends one bit of command or data directly on the command line (SDIO\_CMD) and all data lines (SDIO\_D). The SDIO\_CLK frequency may be between 0 MHz and 20 MHz for MMC card version V3.31, between 0 MHz and 48 MHz for MMC card version V4.2, and between 0 MHz and 25 MHz for SD or SD I/O cards

SDIO\_CMD: This signal is a bidirectional command channel used for initialization of the card and transmission of commands. Commands are sent from the SDIO controller to the card and responses are sent from the card to the host.

SDIO\_D [7: 0]: These signal lines are all bidirectional data channels. The data signal line operates in push-pull mode. Only the card or host drives these signals at a time. By default, only D0 is used for data transmission after power on or reset. The SDIO adapter can be configured with a wider data bus for data transfer, using D0-D3 or D0-D7 (only for MMCV4.2). The SDIO has an internal pull-up to the data signal lines D1-D7. After entering 4-bit mode, the card disconnects the internal pull-ups of D1 and D2 (the internal pull-up of D3 remains unchanged due to the use of CS slice selection in SPI mode). Accordingly, after entering 8-bit mode, the internal pull-ups of D1, D2, and D4-D7 are disconnected (the internal pull-up of D3 remains unchanged due to the use of CS slice selection in SPI mode).

The SDIO adapter is the interface of SD/SD I/O/MMC/CE-ATA and consists of 3 sub-units:

### 31.2.1 Control unit

The control unit includes a power management function and a clock management function for outputting a clock. Power management is controlled by the SDIO\_PWRCTL register to realize power-down and power-on of the power supply. The power saving mode is configured by setting the PWRSAV bit of SDIO\_CLKCR, so that when the bus is idle, SDIO\_CLK is turned off. Clock management generates an SDIO\_CLK clock signal to the card.

### 31.2.2 Command unit

The command unit implements sending and receiving commands to the card. The data transmission flow is controlled by a command state machine (CSM). After a write operation is performed to the SDIO\_CMD register and the start\_cmd bit of the register is set to 1, the command transfer begins. First, a command is sent to the card. This command contains 48 bits and is issued through the SDIO\_CMD line. Each SDIO\_CLK sends one bit of data. This 48-bit command contains a 1-bit start bit, a 1-bit transfer bit, a 6-bit command index (defined by the cmd\_index bit of the SDIO\_CMD register), a 32-bit argument (defined by the SDIO\_CMDARG), a 7-bit CRC, and a 1-bit stop bit. The response from the card is then received, which is divided into a 48-bit short response and a 136-bit long response, both of which are stored in the SDIO\_RESP0-SDIO\_RESP3 registers.

#### ■ Command channel state machine (CPSM)

When the command register is written and the enable bit is set, the command is sent. When the command is sent, the Command Channel State Machine (CPSM) sets the status flag and enters the idle state when no response is required (see figure below). When the response is received, the received CRC code will be compared with the internally generated CRC code, and then the corresponding status flag will be set.

Figure 31-2 SD\_MMC command channel state machine (CPSM)

The command channel state machine performs the following functions based on the CMD register bit values:

1. send\_initialization-Sends an initialization sequence of 80 clocks before sending a command.
2. response\_expected-The expected response to the command. After the command is issued, the command channel state machine receives a 48-bit or 136-bit response and sends it to the SDIO adapter. If the start bit of the card response is not received within the number of clocks programmed in the timeout register, the response timeout and command completion bits are set in the interrupt status register. If the response expected bit is not set, the command complete bit is set in the interrupt status register after the command is issued.

3. response\_length-if this bit is set, a 136-bit response is received; If not set, a 48-bit response is received.

4. check\_response\_crc-If this bit is set, the command channel compares the CRC7 received in the response with the internally generated CRC7. If the two do not match, the response CRC error signal is sent to the bus interface; Set the response CRC error bit in the interrupt status register.

Figure 31-3 SDIO command transfer

### ■ Command format

**Command:** A command is used to start an operation. The host issues addressed commands or broadcast commands to a specified card or all cards (broadcast commands are only suitable for MMC V3.31 or earlier). The commands are transmitted serially on the CMD line. All commands are fixed to 48 bits in length, and the following table gives the general command formats on MMC, SD memory cards, and SDIO cards.

The CE-ATA command is an extension of the MMC V4.2 command, so it has the same format.

The command channel is in half-duplex mode so that commands and responses can be sent and received. If the CPSM is not in the transmit state, the SDIO\_CMD output is in the high impedance state.

The data on SDIO\_CMD is synchronized with the rising edge of SDIO\_CK.

Table 31-2 command format

| Bit     | Width | Value | Description   |
|---------|-------|-------|---------------|
| 47      | 1     | 0     | Start bit     |
| 46      | 1     | 1     | Transfer bit  |
| [45: 0] | 6     | -     | Command Index |
| [39: 8] | 32    | -     | Parameter     |
| [7: 1]  | 7     | -     | CRC7          |
| 0       | 1     | 1     | End bit       |

**Response:** A response is sent to the host by a card with an assigned address. The response is a response to a previously received command. The response is transmitted serially on the CMD line.

SDIO supports 2 response types, both of which have CRC error detection:

- 48-bit short response
- 136-bit long response

If the response does not contain a CRC (such as the response of CMD1), the device driver should ignore the CRC error status.

Table 31-3 short response format

| Bit     | Width | Value | Description   |
|---------|-------|-------|---------------|
| 47      | 1     | 0     | Start bit     |
| 46      | 1     | 1     | Transfer bit  |
| [45: 0] | 6     | -     | Command Index |
| [39: 8] | 32    | -     | Parameter     |
| [7: 1]  | 7     | -     | CRC7          |
| 0       | 1     | 1     | End bit       |

Table 31-4 length response format

| Bit        | Width | Value  | Description                          |
|------------|-------|--------|--------------------------------------|
| 135        | 1     | 0      | Start bit                            |
| 134        | 1     | 0      | Transfer bit                         |
| [133: 128] | 6     | 111111 | Reserved                             |
| [127: 1]   | 127   | -      | CID or CSD (including internal CRC7) |
| 0          | 1     | 1      | End bit                              |

The command register contains the command index (6 bits issued to the card) and the command type; The command itself determines whether a response is required and the type of response: 48-bit or 136-bit. The status flags in the command channel are shown in the following table:

Table 31-5 command channel status flags

| mark     | Description                                                       |
|----------|-------------------------------------------------------------------|
| CMDREND  | Correct CRC for response                                          |
| CCRCFAIL | CRC error in response                                             |
| CMDSENT  | Commands (commands that do not require a response) have been sent |
| CTIMEOUT | Response timeout                                                  |
| CMDACT   | Sending commands                                                  |

The CRC generator calculates the CRC checksum of all bits prior to the CRC code, including the start bit, the transmit bit, the command index, and the command parameter (or card status). For the long response format, the CRC check calculates the first 120 bits of the CID or CSD.

Note that the start bit, the transmit bit, and the 6 reserved bits in the long response format do not participate in the CRC calculation. The CRC check value is a 7-bit value.

### 31.2.3 Data unit

The data unit realizes data transmission between the host and the card. When the data width is 8 bits, the data transmission uses the SDIO\_D [7: 0] signal line; When the data width is 4 bits, the data transmission uses the SDIO\_D [3: 0] signal line; When the data width is 1 bit, the data transmission uses the SDIO\_D [0] signal line. The data transmission flow is controlled by a data state machine (DSM).

#### ■ Data Sending State Machine (DTSM)

The DTSM operates at the SDIO\_CLK frequency, and the card bus signal is synchronized with the rising edge of SDIO\_CLK.

As shown in the figure, the data sending state machine starts data sending two clocks after receiving the response of the data write command; This happens even if the command channel state machine detects an error or responds to a CRC error. If no response is received from the card due to response timeout, no data is transmitted. Depending on the value of the transfer\_mode bit in the command register, the data sending state machine places data on the card data bus in streams or blocks.

Figure 31-4 Data Send State Machine (DTSM)

#### ■ Data Reception State Machine (DRSM)

As shown, the data receiving state machine receives data two clock cycles after the end bit of the data read command, even if the command channel detects a response error or a response CRC error. If the response from the card is not received because the response timed out, the SDIO adapter will not receive the signal that the data transmission is complete; This happens if the command sent is an illegal operation on the card, which prevents the card from starting to read the data transfer. If data is not received before the data timeout, the data receiving state machine signals the data timeout to the SDIO adapter and ends the data transmission. Depending on the value of the transfer\_mode bit in the command register, the data receiving state machine fetches data from the card data bus as a stream or a block.

Figure 31-5 Data receiving state machine (DRSM)

### 31.2.4 SDIO clock control

SDIO mainly has two clock controls, one is the system clock `clk` and the other is `clk_in`. The specific clock description is as follows:

1. `clk`, rising edge valid: system clock,
2. `Cclk_in` rising edge valid: card clock, which needs to satisfy " $clk \geq cclk\_in/10$ "
3. `Cclk_in_drv`: The delayed `clk_in` drives the clock of the card, which is used to control `data_out` and `cmd_out`.
4. `Cclk_in_sample`: The input of the delayed `clk_in` sample card clock, which needs to consider the delay on the PAD, and is used to control the sampling of `ccmd_in` and `cdata_in`
5. The falling edge of `cclk_in` is valid: the falling edge of `clk_in` drives the clock for `stop_clk_neg` and fifo reading and writing

There are also three register bits that can be used for clock processing, namely the `CKSEL`, `SMPEN`, `SMPCLKSEL` bits of `clk`:

1. `CKSEL`: Used to control output commands, data selection
2. `SMPEN`: pre-sampling enable,
3. `SMPCLKSEL`: Clock phase selection, you can select the specific phase of the clock

## 31.3 SDIO AHB interface

The AHB interface generates interrupts and DMA requests and accesses the SDIO interface registers and the data FIFO. It contains a data channel, register decoder, interrupts, and DMA control logic.

### 31.3.1 SDIO interrupts

When at least one status flag is high, the interrupt control logic generates an interrupt request. There is a mask register for selecting conditions that can generate interrupts, and if the corresponding mask flag is set, the corresponding status flag can generate interrupts.

### 31.3.2 SDIO/DMA interface: the process of data transfer between SDIO and memory

SDIO/DMA: The process of data transfer between SDIO and memory.

In the following example, the host controller uses CMD 24 (WRITE\_BLOCK) to transfer 512 bytes from the host to the MMC card, and the DMA controller is used to fill data from memory to the FIFO of the SDIO.

1. Perform the card identification process
2. Increase SDIO\_CK frequency
3. Send CMD7 command to select card
4. Configure DMA2 as follows:
  - a) Enable the DMA2 controller and clear all interrupt flags
  - b) Set the source address register of DMA2 channel 4 as the base address of the memory buffer, and the destination address register of DMA2 channel 4 as the address of the SDIO\_FIFO register
  - c) Set DMA2 channel 4 control register (memory increment, non-peripheral increment, data width of peripheral and source is word width)
  - d) Enable DMA2 Channel 4
5. Send CMD24 (WRITE\_BLOCK) as follows:
  - a) Set the SDIO data length register (the SDIO data clock register should be set before performing the card identification process)
  - b) Set the SDIO parameter register to the address in the card to which data needs to be transferred
  - c) Set the SDIO command register: CmdIndex is set to 24 (WRITE\_BLOCK); WaitRest is set to 1 (SDIO card host waits for response); Start\_cmd is set to 1 (enables the SDIO card host to send commands), keeping other fields at their reset values.
  - d) Wait for the CD (end of command) to interrupt, and then set the SDIO data register: DTEN is set to 1 (enable the SDIO card host to send data); DTDIR is set to 0 (controller to card direction); DTMODE is set to 0 (block data transfer); DMAEN is set to 1 (enable DMA); DBLOCKSIZE is set to 9 (512 bytes); Other fields do not need to be set.
  - e) Wait for SDIO\_STA [10] = 1.
6. Query the enable status register of the DMA channel to confirm that no channel is still enabled.

## 31.4 Card Function Description

### 31.4.1 Card recognition mode

In card recognition mode, the host resets all the cards, detects the operating voltage range, identifies the cards and sets a relative address (RCA) for each card on the bus. In the card recognition mode, all data communications use only the command signal line (CMD).

### 31.4.2 Card reset

The GO\_IDLE\_STATE command (CMD0) is a software reset command that puts the multimedia card and SD memory into an idle state. The IO\_RW\_DIRECT command (CMD52) resets the SD I/O card. After power-on or after CMD0 is executed, the outputs of all cards are in a high impedance state, and

all cards are initialized to a default relative card address (RCA = 0x0001) and default driver register setting (lowest speed, maximum current driving capacity).

### 31.4.3 Operating voltage range validation

All cards can communicate with the SDIO card host using any specified range of voltages, and the minimum and maximum supportable voltage VCC values are defined by the operating condition register (OCR) on the card.

A card whose internal memory stores a card identification number (CID) and card specific data (CSD), which can only be transmitted under data transmission VCC conditions. When the SDIO card host module is inconsistent with the VCC range of the card, the card will not be able to complete the identification cycle or send CSD data; Therefore, when the VCC range does not match, the SDIO card host may use the following special commands to identify and reject the card: SEND\_OP\_COND (CMD1), SD\_APP\_OP\_COND (ACMD41 of the SD memory card), and IO\_SEND\_OP\_COND (CMD5 of the SD I/O card). The SDIO card host will generate the required VCC voltage when executing these commands. Cards that cannot transmit data in the specified voltage range will be disconnected from the bus and entered into an inactive state.

Using these commands that do not contain a voltage range as an operand, the SDIO card host can query each card and put cards that are not within this range into an inactive state before determining a common voltage range. The SDIO card host can make such a query when the SDIO card host can select a common voltage range or when the user needs to know if the card is usable.

### 31.4.4 Card identification process

There is a difference in the card recognition process between multimedia cards and SD cards; For multimedia cards, the card identification process starts at the clock frequency F<sub>od</sub>, and all SDIO\_CMD outputs are driven open circuit, allowing parallel connection of cards in this process. The identification process is as follows:

1. The bus is activated
2. The SDIO card host broadcast transmits the SEND\_OP\_COND (CMD1) command and receives the operating conditions
3. The resulting response is a "line AND" of the operating condition register contents of all cards
4. Incompatible cards are placed inactive
5. SDIO card host broadcast sends ALL\_SEND\_CID (CMD2) to all active cards
6. All active cards simultaneously send their CID numbers serially, and those cards that detect that the output CID bits do not match the data on the command line must stop sending and wait for the next identification cycle. In the end, only one card can successfully transmit the complete CID to the SDIO card host and enter the identification state.
7. The SDIO card host sends a SET\_RELATIVE\_ADDR (CMD3) command to this card. This new address is called the relative card address (RCA), which is shorter than the CID and is used to address the card. At this point, the card goes to standby and no longer responds to the new identification process, and its output drive changes from open circuit to push-pull mode.
8. The SDIO card host repeats steps 5 through 7 above until a timeout condition is received.

For SD cards, the card identification process starts at the clock frequency  $F_{od}$ , and all SDIO\_CMD outputs are push-pull drive instead of open circuit drive. The identification process is as follows:

1. The bus is activated
2. The SDIO card host broadcasts to send the SEND\_APP\_OP\_COND (ACMD41) command
3. The resulting response is the contents of the operating condition registers for all cards
4. Incompatible cards are placed inactive
5. SDIO card host broadcast sends ALL\_SEND\_CID (CMD2) to all active cards
6. All activated cards send back their unique card identification number (CID) and enter the identification status.
7. The SDIO card host sends the SET\_RELATIVE\_ADDR (CMD3) command and an address to an active card. This new address is called the relative card address (RCA), which is shorter than the CID and is used to address the card. At this point, the card goes to standby mode. The SDIO card host can send this command again to change the RCA, and the card's RCA will be the last assignment.
8. The SDIO card host repeats steps 5 through 7 above for all activated cards.

#### 31.4.5 Write data block

When the write block command (CMD24-27) is executed, the host transfers one or more data blocks from the host to the card, and a CRC code is transferred at the end of each data block. A card that supports write block commands should always be able to receive blocks defined by WRITE\_BLK\_LEN. If the CRC check is erroneous, the card indicates the error through the SDIO\_D signal line, the transferred data is discarded and not written, and all subsequent (in multi-block write mode) transferred data blocks are ignored.

If the host transmits partial data and the accumulated data length is not aligned with the data block, the card will detect a block misalignment error before the first misaligned block (setting the ADDRESS\_ERROR error bit in the status register) when block misalignment is not allowed (without setting the parameter WRITE\_BLK\_MISALIGN of the CSD). When the host attempts to write a write-protected area, the write operation will also be aborted, at which time the card sets the WP\_VIOLATION bit.

Setting the CID and CSD registers does not need to set the block length in advance, and the transmitted data is also protected by CRC. If part of the CSD or CID register is stored in the ROM, this part that cannot be changed must be consistent with the corresponding part of the receive buffer. If there is an inconsistency, the card will report an error without modifying the contents of any register. Some cards take a long or even unpredictable time to complete writing a data block. After receiving a data block and completing the CRC check, the card starts writing operations. If its write buffer is full and it can no longer receive new data from the new WRITE\_BLOCK command, it will pull the SDIO\_D signal line down. The host can check the status of the card at any time using SEND\_STATUS (CMD13), and the card will return to its current status. The READY\_FOR\_DATA status bit indicates whether the card can receive new data or whether a write operation is still in progress. The host can use CMD7 (Select Another Card) to unselect a card and put the card in the disconnected state, which can release the SDIO\_D signal line without interrupting the outstanding write operation; When a card is re-selected, if the write operation is

still in progress and the write buffer is still unavailable, it will re-indicate the busy state by pulling down the SDIO\_D signal line.

#### 31.4.6 Read data block

In read block mode, the basic unit of data transmission is a data block, the size of which is defined in the CSD (READ\_BL\_LEN). If READ\_BL\_PARTIAL is set, a smaller data block can also be transferred. A smaller data block means that the start and end addresses are completely contained in a physical block. READ\_BL\_LEN defines the size of the physical block. To ensure the correctness of data transmission, there is a CRC check code after each data block. CMD 17 (READ\_SINGLE\_BLOCK) starts a read block operation, and the card returns to the transmission state after the transmission is completed. CMD 18 (READ\_MULTIPLE\_BLOCK) initiates a read operation of multiple consecutive data blocks at a time.

The host may abort the multi-block read operation at any time, regardless of the type of operation. Send a stop transmission command to abort the operation.

If the card detects an error (e.g. out of bounds, address misalignment, or internal error) during a multi-block read operation (either type), it will stop data transmission and remain in the data state; At this time, the host must send a stop transmission command to abort the operation. Report a read error in the response to the stop transmission command.

If when the host sends the stop transmission command, the card has finished transmitting the last data block of a certain number of data block operations, because the card is no longer in the data state at this time, the host will receive a response with an illegal command. If the host transmits part of the data block and the accumulated data length cannot be aligned with the physical block and block misalignment is not allowed, the card detects a block alignment error when the first misaligned block occurs and sets the ADDRESS\_ERROR error flag in the status register.

#### 31.4.7 Erasure: Group and Sector Erasure

The erase unit of the multimedia card is the erase group, which is calculated by write data block, and the write data block is the basic write unit of the card. The size of the erase group is a card-specific parameter, defined in the CSD.

The host can erase a continuous range of erase groups, and there are three steps to start the erase operation.

First, the host uses the ERASE\_GROUP\_START (CMD35) command to define the start address of the continuous range, then uses the ERASE\_GROUP\_END (CMD36) command to define the end address of the continuous range, and finally sends the ERASE command ERASE (CMD38) to start the ERASE operation. The address field of the erase command is the erase group address in bytes. The card will discard the portion that is not aligned with the size of the erase group and align the address boundary to the boundary of the erase group.

If the erase command is not received as described above, the card sets the ERASE\_SEQ\_ERROR bit in the status register and waits for the first step again.

If a command other than the SEND\_STATUS and erase command is received, the card sets the ERASE\_RESET bit in the status register, cancels the erase sequence and executes a new command.

### 31.4.8 Wide bus selection and de-selection

The wide bus (4-bit bus width) operation mode can be selected or not selected by the SET\_BUS\_WIDTH (ACMD6) command, and the default bus width is 1 bit after power-up or after the GO\_IDLE\_STATE (CMD0) command. The SET\_BUS\_WIDTH (ACMD6) command is only valid in the transfer state, i.e. the bus width can only be changed after the card has been selected using the SELECT/DESELECT\_CARD (CMD7) command.

### 31.4.9 Protection management

The SDIO card host module supports three protection methods:

1. Internal card protection (in-card management)
2. Mechanical write protection switch (only managed by SDIO card host module)
3. Card locking operation of password management

### 31.4.10 Card status register

Response format R1 contains a 32-bit card status field, which is used to send card status information to the card host (this information may be stored in a local status register). Unless otherwise specified, the status returned by the card is always related to the previous command.

The abbreviations in the table for types and purge condition fields are defined as follows:

Type:

- E: Error bit
- S: Status bit
- R: detection bit and set according to the actual command response
- X: detection bit, set during the execution of the command. The SDIO card host checks the status of the card by sending a status command to read out these bits.

Clear condition:

- A: According to the current status of the card
- B: Always related to the previous command. The correct command is received to clear (with a delay of one command).
- C: Read to clear

Table 31-6 card status

| Bit | Pin name             | Type  | Value                         | Description                                                                                                                                                                                                                                                                                                                                                | Clear condition |
|-----|----------------------|-------|-------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|-----------------|
| 31  | ADDRESS_OUT_OF_RANGE | E R X | '0' = no error<br>'1' = error | A multi-block or stream read/write operation (even starting from a legitimate address) attempts to read or write a portion that exceeds the capacity of the card.                                                                                                                                                                                          | C               |
| 30  | ADDRESS_ISALIGN      |       | '0' = no error<br>'1' = error | The first data block defined by the address parameter in the command (compared to the current data block length) is not aligned with the physical block of the card.<br>A multi-block or data stream read/write operation (even starting from a legitimate address) attempts to read or write a block of data that is not aligned with the physical block. | C               |
| 29  | BLOCK_LEN_ERROR      |       | '0' = no error<br>'1' = error | The parameters of the SET_BLOCKLEN command exceed the maximum allowable range of the card, or the previously defined data block length is illegal for the current command (for example, the host issues a write command, the current block length is less than the minimum allowed length of the card,                                                     | C               |

|        |                        |     |                                                                                                                                                            |                                                                                                                                                                                                                                                                                                                            |   |
|--------|------------------------|-----|------------------------------------------------------------------------------------------------------------------------------------------------------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|---|
|        |                        |     |                                                                                                                                                            | and at the same time, it is not allowed to write some data blocks).                                                                                                                                                                                                                                                        |   |

### 31.4.11 SD status register

The SD state contains status bits related to specific functions of the SD memory card and some status bits related to future applications. The length of the SD state is a 512-bit data block. Upon receipt of the ACMD13 command (CMD55, then CMD13), the contents of this register are transferred to the SDIO card host. ACMD13 commands can only be sent when the card is in the transmission state (the card has been selected).

X The following table defines different SD status register information. The abbreviations for types and clear condition fields in the table define the following types:

- E: Error bit
- S: status bit
- R: detection bit and set according to the actual command response
- X: detection bit, set during the execution of the command. The SDIO card host checks the status of the card by sending a status command to read out these bits.

Clear condition:

- A: According to the current status of the card
- B: Always related to the previous command. The correct command is received to clear (with a delay of one command).
- C: Clear after reading

Table 31-7 SD Status

| Bit      | Pin name      | Type | Value                                                                          | Description                                                                                         | Clear condition |

| 311: 0   | Reserved for manufacturers |    |                                                                                                                                                                                                   |                                                                                                                                                                                                                                                                               |   |

### SIZE\_OF\_PROTECTED\_AREA

Standard capacity cards and high capacity cards set this bit differently. For a standard capacity card, the capacity of the protected area is calculated by:

Protected area = SIZE\_OF\_PROTECTED\_AREA \* MULT \* BLOCK\_LEN

The unit of SIZE\_OF\_PROTECTED\_AREA is MULT \* BLOCK\_LEN.

For high capacity cards, the capacity of the protected area is calculated by:

Protected area = SIZE\_OF\_PROTECTED\_AREA

The unit of SIZE\_OF\_PROTECTED\_AREA is bytes.

### Speed\_CLASS

These 8 bits indicate the type of speed and the value that can be calculated by  $PW/2$  (PW is the performance of writing).

Table 31-8 Speed Type Code

| Speed_CLASS | Numerical Definition |
|-------------|----------------------|
| 00h         | Type 0               |
| 01h         | Type 2               |
| 02h         | Type 4               |
| 03h         | Type 6               |
| 04h-FFh     | Reserved             |

### PERFORMANCE\_MOVE

These 8 bits indicate mobility performance (Pm) in units of 1 MB/sec. If the card does not move data using RU (unit of record), Pm should be considered to be infinite. Setting this field to FFh means infinity.

Table 31-9 mobile performance codes

| Speed_CLASS | Numerical Definition |
|-------------|----------------------|
| 00h         | Undefined            |
| 01h         | 1 MB/S               |
| 02h         | 2 MB/S               |
| .....       | .....                |
| Feh         | 254 MB/sec           |
| FFh         | Infinity             |

**AU\_Size**

These 4 bits indicate the length of the AU, and the value is a multiple of the power of 2 of 16K bytes.

Table 31-10 AU\_SIZE Code

| Speed_CLASS | Numerical Definition |
|-------------|----------------------|
| 00h         | Undefined            |
| 01h         | 16 KB                |
| 02h         | 32 KB                |
| 03h         | 64 KB                |
| 04h         | 128 KB               |
| 05h         | 256 KB               |
| 06h         | 512 KB               |
| 07h         | 1 MB                 |
| 08h         | 2 MB                 |
| 09h         | 4 MB                 |
| AH-Fh       | Reserved             |

Depending on the card capacity, the maximum AU length is defined by the table below. The card may set an arbitrary AU length between the RU length and the maximum AU length.

Table 31-11 Maximum AU Length

| Size              | 16-64 MB | 128-256 MB | 512 MB | 1-32 GB |
|-------------------|----------|------------|--------|---------|
| Maximum AU length | 512 KB   | 1 MB       | 2 MB   | 4 MB    |

**ERASE\_SIZE**

This 16-bit field gives NERASE, and ERASE\_TIMEOUT defines the timeout when NERASE AUs are erased. The host should determine the appropriate number of AUs to erase in one operation so that the host can display the progress of the erase operation. If the domain is 0, the timeout calculation of erasure is not supported.

Table 31-12 ERASE\_SIZE Code

| ERase_CLASS | Numerical Definition                           |
|-------------|------------------------------------------------|
| 0000h       | Timeout operation for erasure is not supported |
| 0001h       | 1 AU                                           |
| 0002h       | 2 AU                                           |
| 0003h       | 3 AU                                           |
| .....       | .....                                          |
| FFFFh       | 65535 AU                                       |

**ERase\_TIMEOUT**

These 6 bits give TERASE, ERASE\_SIZE indicates that a plurality of AUs are erased, and this value gives the erase timeout from the offset. The range of ERASE\_TIMEOUT can be defined to a maximum of 63 seconds, and the manufacturer of the card can select an appropriate combination of ERASE\_SIZE and ERASE\_TIMEOUT according to the specific implementation, determining ERASE\_TIMEOUT first and then ERASE\_SIZE.

Table 31-13 erase timeout code

| ERase_TIMEOUT | Numerical Definition                        |
|---------------|---------------------------------------------|
| 00            | Timeout operation not supported for erasure |
| 01            | 1 sec                                       |
| 02            | 2 seconds                                   |
| 03            | 3 seconds                                   |
| .....         | .....                                       |
| 63            | 63 seconds                                  |

**ERase\_OFFSET**

These two bits give TOFFSET, which is meaningless when ERASE\_SIZE and ERASE\_TIMEOUT are both 0.

Table 31-14 Erase Offset Code

| ERase_OFFSET | Numerical Definition |
|--------------|----------------------|
| 0            | 0 seconds            |
| 1            | 1 sec                |
| 2            | 2 seconds            |
| 3            | 3 seconds            |

**31.4.12 I/O Mode of SD****I/O interrupt for SD**

In order to allow the SD I/O card to interrupt the MMC/SD module, there is a pin with interrupt function on the SD interface-pin 8. In 4-bit SD mode, this pin is SDIO\_D1, and the card uses it to submit an interrupt application to the MMC/SD module. The interrupt function is optional for each card or function within the card. The interrupt of SD I/O is active level, that is, the interrupt signal line must remain active level (low) before being recognized and receiving a response from the MMC/SD module, and inactive level (high) after the end of the interrupt process. After the MMC/SD module serves the interrupt request, the interrupt status bit can be cleared by writing the appropriate bit to the internal register of the SD I/O card through an I/O write operation. The interrupt output of all SD I/O cards is active low, and pull-up resistors are provided on all data lines (SDIO/D [3: 0]) of the MMC/SD module. The MMC/SD module samples pin 8 (SDIO\_D/IRQ) during the interrupt phase and performs interrupt detection, and the value on this signal line will be ignored at other times.

Both memory operations and I/O operations have interrupt phases, and the definition of the interrupt phase of a single data block operation is different from that of a plurality of data block transfer operations.

**I/O suspension and resumption of SD**

In a multifunctional SD I/O card or a card having both I/O and memory functions, a plurality of devices (I/O and memory) share the MMC/SD bus. In order to enable multiple devices in the MMC/SD module to share the bus, the SD I/O card and the composite card can selectively implement the concept of pause/resume; If a card supports pause/resume, the MMC/SD module can temporarily stop the data transfer operation (pause) of one function or memory, thereby giving up the bus to another function or memory having a higher priority, and resuming the previously suspended transmission after this higher priority transmission is complete. Actions that support pause/resume are optional. There are the following steps to perform a pause/resume operation on the MMC/SD bus:

1. Determine the current function of the SDIO\_D [3: 0] signal line
2. Request a low-priority or slow operation pause

3. Wait for the pause operation to complete and confirm that the device has been paused
4. Start high-priority transmission
5. Wait for high-priority transmission to end
6. Resume suspended operations

### **SD I/O ReadWait**

The optional read wait (RW) operation is only available in the 1-bit or 4-bit mode of the SD card. The read wait operation allows the MMC/SD module to ask a card to temporarily stop data transfer while it is reading multiple registers (IO\_RW\_EXTENDED, CMD53), while allowing the MMC/SD module to send commands to other functions in the SD I/O device. To determine whether a card supports the read wait protocol, the MMC/SD module should check the internal registers of the card. The read wait time is related to the interrupt phase

## **31.4.13 Commands and responses**

### **31.4.13.1 Apply dependent and generic commands**

SD card host module system is used to provide a standard interface suitable for various application types, but at the same time, it should take into account the functions of specific users and applications. Therefore, two types of general commands are defined in the standard: application-related commands (ACMD) and general commands (GEN\_CMD).

When the card receives the APP\_CMD (CMD55) command, the card expects the next command to apply the relevant command. The application-related command (ACMD) has the same format structure as a normal MMC and can use the same CMD number because it appears after the APP\_CMD (CMD55), so the card recognizes it as an ACMD command. If APP\_CMD (CMD55) is not followed by an already defined application-related command, it is considered a standard command; Example: There is an SD\_STATUS (ACMD13) application related command. If CMD13 is received immediately after APP\_CMD (CMD55), it is interpreted as SD\_STATUS (ACMD13); However, if the card receives CMD7 immediately after APP\_CMD (CMD55) and this card does not define ACMD7, it will be interpreted as a standard CMD7 (SELECT/DESELECT\_CARD) command.

If you want to use the manufacturer-defined ACMD, the SD card host needs to do the following operations:

1. Send the APP\_CMD (CMD55) command

The card sends back a response to the multimedia/SD card module indicating that the APP\_CMD bit is set and waits for the ACMD command.

2. Send the specified ACMD

The card sends back a response to the multimedia/SD card module indicating that the APP\_CMD bit is set and that the received command has been correctly parsed according to the ACMD command; If a non-ACMD command is sent, the card will follow the normal MMC command and clear the APP\_CMD bit of the status register in the card.

If an illegal command (whether ACMD or CMD) is sent, it will be error handled according to the standard illegal MMC command.

The bus operation procedure of the GEN\_CMD command is the same as that of the single data block read/write command (WRITE\_BLOCK, CMD24 or READ\_SINGLE\_BLOCK, CMD17); At this time, the parameters of the command represent the direction of data transmission instead of the address, and the data block has a user-defined format and meaning.

Before sending the GEN\_CMD (CMD56) command, the card must be selected (the state machine is in the transmission state) and the length of the data block is defined by SET\_BLOCKLEN (CMD16). The response to the GEN\_CMD (CMD56) command is in R1b format.

### 31.4.13.2 Command Type

There are four different types of application-dependent and generic commands:

1. Broadcast Command (BC): Sent to all cards, no response returned.
2. Broadcast command with response (BCR): Send to all cards and receive responses returned from all cards at the same time.
3. Command (AC) with addressing (point-to-point): sent to the selected card, data transmission is not included on the SDIO\_D signal line.
4. Data Transmission Command (AC) with Addressing (Point-to-Point): Send to the selected card, including data transmission on the SDIO\_D signal line.

### 31.4.13.3 Command format

See Command Format Table

## Commands for MMC/SD Card Module

Table 31-15 Block Transfer Based Write Commands

| CMD Index | Type | Parameter                                       | Response format | Written              | Description                                                                                                                                                                                                                                |
|-----------|------|-------------------------------------------------|-----------------|----------------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| CMD23     | ac   | [31: 16] = 0<br>[15: 0] = number of data blocks | R1              | SET_BLOCK_Count      | Define the number of transport blocks needed in subsequent multi-block read or write commands                                                                                                                                              |
| CMD24     | adtc | [31: 0] = data address                          | R1              | Write_BLOCK          | Write a block of the length selected by the SET_BLOCKLEN command                                                                                                                                                                           |
| CMD25     | adtc | [31: 0] = data address                          | R1              | Write_MULTIPLE_BLOCK | Continuously write blocks of data until a STOP_TRANSMISSION command is received or the specified number of blocks is reached                                                                                                               |
| CMD26     | adtc | [31: 0] = padding bit                           | R1              | PROGRAM_CID          | Program the identification register of the card. You can only send this command once per card. There are hardware mechanisms in the card to prevent multiple programming operations. Usually this command is reserved for the manufacturer |
| CMD27     | adtc | [31: 0] = padding bit                           | R1              | PROGRAM_CSD          | Program the programmable bits in the CSD of the card.                                                                                                                                                                                      |
| CMD28     | ac   | [31: 0] = data address                          | R1b             | SET_Write_PROT       | If the card has write protection, this command sets the write protection bits for the specified group. The write protection feature is set in the special data area of the card (WP_GRP_SIZE).                                             |

|       |          |                                        |     |                 |                                                                                                                 |
|-------|----------|----------------------------------------|-----|-----------------|-----------------------------------------------------------------------------------------------------------------|
| CMD29 | ac       | [31: 0] = data address                 | R1b | CLR_Write_PROT  | If the card has write protection, this command clears the specified set of write protection bits                |
| CMD30 | adtc     | [31: 0] = write protected data address | R1  | Send_WRITE_PROT | If the card has write protection, this command requires the card to send the status of the write protection bit |
| CMD31 | Reserved |                                        |     |                 |                                                                                                                 |

Table 31-16 Write Protection Commands Based on Block Transfer

| CMD Index | Type     | Parameter                              | Response format | Written         | Description                                                                                                     |
|-----------|----------|----------------------------------------|-----------------|-----------------|-----------------------------------------------------------------------------------------------------------------|
| CMD28     | ac       | [31: 0] = data block address           | R1b             | SET_WritE_PORT  | Define the number of transport blocks needed in subsequent multi-block read or write commands                   |
| CMD29     | ac       | [31: 0] = data address                 | R1b             | CLR_Write_PORT  | Write a block of the length selected by the SET_BLOCKLEN command                                                |
| CMD30     | adtc     | [31: 0] = write protected data address | R1              | Send_WRITE_PROT | If the card has write protection, this command requires the card to send the status of the write protection bit |
| CMD31     | Reserved |                                        |                 |                 |                                                                                                                 |

Table 31-17 erase command

| CMD Index             | Type                                                                                                                   | Parameter                              | Response format | Written         | Description                                                                                                     |
|-----------------------|------------------------------------------------------------------------------------------------------------------------|----------------------------------------|-----------------|-----------------|-----------------------------------------------------------------------------------------------------------------|
| CMD32<br>...<br>CMD34 | Reserve. These command codes cannot be used for backward compatibility with older versions of the Media Card Protocol. |                                        |                 |                 |                                                                                                                 |
| CMD35                 | ac                                                                                                                     | [31: 0] = data address                 | R1b             | CLR_Write_PORT  | Write a block of the length selected by the SET_BLOCKLEN command                                                |
| CMD36                 | adtc                                                                                                                   | [31: 0] = write protected data address | R1              | Send_WRITE_PROT | If the card has write protection, this command requires the card to send the status of the write protection bit |
| CMD37                 | Reserve. For backward compatibility with older versions of the media card protocol, this command code cannot be used   |                                        |                 |                 |                                                                                                                 |
| CMD38                 | ac                                                                                                                     | [31: 0] = filler                       | R1              | ERASE           | Erase the previously selected data block                                                                        |

Table 31-18 I/O Mode Commands

| CMD Index | Type     | Parameter                                                                                            | Response format | Written      | Description                                                                                                                                                                                                                                                                                                                    |
|-----------|----------|------------------------------------------------------------------------------------------------------|-----------------|--------------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| CMD39     | ac       | [31: 16] = RCA<br>[15] = register write flag<br>[14: 8] = register address<br>[7: 0] = register data | R4              | FAST_IO      | For writing and reading 8-bit (register) data fields. This command specifies a card and register, and also provides data to be written if the write flag is set. The R4 response contains data read from the specified register. This command accesses application-related registers that are not defined in the MMC standard. |
| CMD40     | bcr      | [31: 0] = write protected data address                                                               | R5              | GO_IRO_STATE | Set the system in interrupt mode.                                                                                                                                                                                                                                                                                              |
| CMD41     | Reserved |                                                                                                      |                 |              |                                                                                                                                                                                                                                                                                                                                |

Table 31-19 lock command

| CMD In-<br>dex          | Type     | Parameter             | Re-<br>sponse<br>format | Written     | Description                                                                                                      |
|-------------------------|----------|-----------------------|-------------------------|-------------|------------------------------------------------------------------------------------------------------------------|
| CMD42                   | adtc     | [31: 0] = padding bit | R1b                     | LOCK_Unlock | Set/clear the password or lock/unlock the card. The length of the data block is set by the SET_BLOCKLEN command. |
| CMD43<br>.....<br>CMD54 | Reserved |                       |                         |             |                                                                                                                  |

Table 31-20 related commands

| CMD In-<br>dex          | Type                       | Parameter                               | Re-<br>sponse<br>format | Written | Description                                                                                                                                                                                           |
|-------------------------|----------------------------|-----------------------------------------|-------------------------|---------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| CMD55                   | ac                         | [31: 16] = RCA<br>[15: 0] = padding bit | R1                      | APP_CMD | Indicates that the next command of the card is to apply the related command instead of the standard command                                                                                           |
| CMD56                   | adtc                       | [31: 1] = padding bit<br>[0] = RD/WR    |                         |         | In general purpose or application-related commands, either for transferring a data block into or reading a data block from the card. The length of the data block is set by the SET_BLOCKLEN command. |
| CMD57<br>...<br>CMD59   | Reserved                   |                                         |                         |         |                                                                                                                                                                                                       |
| CMD60<br>.....<br>CMD63 | Reserved for manufacturers |                                         |                         |         |                                                                                                                                                                                                       |

## 31.5 Response format

All responses are transmitted over the SDIO\_CMD signal line via the MCCMD command. The transmission of a response always starts at the far left of the bit string corresponding to the response word, the length of which depends on the type of response.

A response always has a start bit (always 0) followed by the direction bit of transmission (card = 0). The numerical values denoted x in the table below represent a variable portion. All responses are CRC protected except for the R3 response type. Each command codeword has an end bit (always 1).

There are 7 response types, and their formats are defined as follows:

### 31.5.1 R1 (normal response command)

Code length = 48 bits. Bit 45: 40 indicates the command index to be responded to, and its value ranges from 0 to 63. The status of the card is encoded by 32 bits.

Table 31-21 R1 Response

| Bit      | Domain width | Value | Description   |
|----------|--------------|-------|---------------|
| 47       | 1            | 0     | Start bit     |
| 46       | 1            | 0     | Transfer bit  |
| [45: 40] | 6            | X     | Command Index |
| [39: 8]  | 32           | X     | Card status   |
| [7: 1]   | 7            | X     | CRC7          |
| 0        | 1            | 1     | End bit       |

### 31.5.2 R1b

Same format as R1, but with the option to send a busy signal on the data line. Upon receipt of these commands, the card may become busy depending on the status before the command was received.

### 31.5.3 R2 (CSD, CSD register)

Code length = 136 bits. The contents of the CID register will be issued as a response to CMD2 and CMD10. The contents of the CSD register will be issued as a response to CMD9. The card only sends out the bits of CID and CSD [127 ... 1], and bit 0 of these registers is replaced by the end bit of the response at the receiving end. The card indicates that it is performing an erase operation by pulling MCDAT low; The actual erase operation can take very long, and the host can send a CMD7 command to unselect this card.

Table 31-22 R2 Response

| Bit        | Domain width | Value    | Description   |
|------------|--------------|----------|---------------|
| 135        | 1            | 0        | Start bit     |
| 134        | 1            | 0        | Transfer bit  |
| [133: 128] | 6            | '111111' | Command Index |
| [127: 1]   | 127          | X        | Card status   |
| 0          | 1            | 1        | End bit       |

### 31.5.4 R3 (OCR register)

Code length = 48 bits. The contents of the OCR register will be issued as a response to CMD1. The definition of the level code is: limited voltage window = low, card busy = low.

Table 31-23 R3 Response

| Bit      | Domain width | Value    | Description   |
|----------|--------------|----------|---------------|
| 47       | 1            | 0        | Start bit     |
| 46       | 1            | 0        | Transfer bit  |
| [45: 40] | 6            | '111111' | Reserved      |
| [39: 8]  | 32           | X        | OCR registers |
| [7: 1]   | 7            | '111111' | Reserved      |
| 0        | 1            | 1        | End bit       |

### 31.5.5 R4 (Fast I/O)

Code length = 48 bits. The parameter field contains the RCA of the specified card, the address to be read out or written to the register, and its contents.

Table 31-24 R4 Response

| Bit                      | Domain width | Value    | Description                       |
|--------------------------|--------------|----------|-----------------------------------|
| 47                       | 1            | 0        | Start bit                         |
| 46                       | 1            | 0        | Transfer bit                      |
| [45: 40]                 | 6            | '111111' | Reserved                          |
| [39: 8] Parameter Domain | [31: 16]     | 16       | RCA                               |
|                          | [15: 8]      | 8        | Register Address                  |
|                          | [7: 0]       | 8        | Read the contents of the register |
| [7: 1]                   | 7            | '111111' | CRC7                              |

|   |   |   |         |
|---|---|---|---------|
| 0 | 1 | 1 | End bit |
|---|---|---|---------|

### 31.5.6 R4b

Suitable for SD I/O cards only: An SDIO card will return a unique SDIO response R4 after receiving CMD5.

Table 31-25 R4b Response

| Bit                      |          | Domain width | Value | Description             |
|--------------------------|----------|--------------|-------|-------------------------|
| 47                       |          | 1            | 0     | Start bit               |
| 46                       |          | 1            | 0     | Transfer bit            |
| [45: 40]                 |          | 6            | X     | Reserved                |
| [39: 8] Parameter Domain | [39]     | 1            | X     | Card ready              |
|                          | [38: 36] | 3            | X     | Number of I/O functions |
|                          | [35]     | 1            | X     | Current memory          |
|                          | [34: 32] | 3            | X     | Padding bit             |
|                          | [31: 8]  | 24           | X     | I/O ORC                 |
| [7: 1]                   |          | 7            | X     | Reserved                |
| 0                        |          | 1            | 1     | End bit                 |

When an SD I/O card receives the command CMD5, the I/O portion of the card is enabled and can normally respond to all subsequent commands. The enabled state of the I/O card will remain until the next reset, power down, or receipt of the CMD52 command for I/O reset. Note that an SD card containing only memory functions can respond to the CMD5 command, and its correct response can be: current memory = 1, number of I/O functions = 0. An SD card designed according to the SD memory card specification version 1.0 containing only memory functions can detect the CMD5 command as an illegal command and do not respond to it. A host that can handle the I/O card will send a CMD5 command, and if the card returns a response R4, the host will determine the configuration of the card based on the data in the R4 response.

### 31.5.7 R5 (Interrupt Request)

For MMC only. Code length = 48 bits. If this response is generated by the host, the RCA domain in the parameter is 0x0.

Table 31-26 R5 Response

| Bit                      |          | Domain width | Value    | Description                             |
|--------------------------|----------|--------------|----------|-----------------------------------------|
| 47                       |          | 1            | 0        | Start bit                               |
| 46                       |          | 1            | 0        | Transfer bit                            |
| [45: 40]                 |          | 6            | '111111' | CMD40                                   |
| [39: 8] Parameter Domain | [31: 16] | 16           | X        | RCA of successful card or host [31: 16] |
|                          | [15: 0]  | 16           | X        | Undefined. Can be used as interrupt     |
| [7: 1]                   |          | 7            | X        | CRC7                                    |
| 0                        |          | 1            | 1        | End bit                                 |

### 31.5.8 R6 (Interrupt Request)

Works with SD I/O cards only. This is a normal response of a memory device to a CMD3 command.

Table 31-27 R6 Response

| Bit                      |          | Domain width | Value    | Description                              |
|--------------------------|----------|--------------|----------|------------------------------------------|
| 47                       |          | 1            | 0        | Start bit                                |
| 46                       |          | 1            | 0        | Transfer bit                             |
| [45: 40]                 |          | 6            | '101000' | CMD40                                    |
| [39: 8] Parameter Domain | [31: 16] | 16           | X        | RCA of successful card or host           |
|                          | [15: 0]  | 16           | X        | Undefined. Can be used as interrupt data |
| [7: 1]                   |          | 7            | X        | CRC7                                     |
| 0                        |          | 1            | 1        | End bit                                  |

When a CMD3 command is sent to a card with only I/O function, the status bit [23: 8] of the card changes; At this point, the 16 bits in the response will be the value in the SD card with only I/O function:

- Bit 15 = COM\_CRC\_ERROR
- Bit 14 = ILLEGAL\_COMMAND
- Bit 13 = ERROR
- Bit [12: 0] = reserved

## 31.6 Programming sequence

### 31.6.1 Card identification

After the host is reset, it enters card recognition mode and looks for a new card on the bus. In card identification mode, the host resets all cards, verifies the operating voltage range, identifies the cards and asks for the relative card address (RCA) of each card. This operation is done separately on each card's own command signal line CMD. All data communications in card recognition mode use only the command signal line (CMD).

During card identification, the card should operate with a clock frequency of the clock rate FOD (400 kHz).

#### 31.6.1.1 Card reset

The command GO\_IDLE\_STATE (CMD0) is a software reset command and sets the MMC and SD memory cards into an Idle State regardless of the current card status. The reset command (CMD0) is only used for the memory or memory portion of the combination card. To reset only the I/O portion of the I/O card or combination card, write 1 to the RES bit of the CCCR using CMD52. Cards in Inactive State are not affected by this command.

After the host is powered on, all cards are in Idle State (Idle State), including cards that have been in Inactive State before. After power-on or CMD0, the CMD line of all cards is in input mode, waiting for the start bit of the next command. These cards are initialized with the default relative card address (RCA) and driven with the default clock frequency of 400 kHz.

#### 31.6.1.2 Operating voltage range verification

When communication begins between the host and the card, the host may not know the voltage the card supports, and the card may not know whether the host can provide the voltage it supports. To verify the voltage, the following commands are all defined in the relevant specifications. Commands defined in the protocol specification include: SEND\_OP\_COND (CMD1 for MMC),

SD\_SEND\_OP\_COND (ACMD41 for SD memory cards), IO\_SEND\_OP\_COND (CMD5 for SD I/O cards), which provide a mechanism for the host to identify and reject cards that do not match the VCC range required by the host. This is achieved by the host sending the required VCC voltage window as an operand of this command. If the card cannot transmit data within the specified range, it must be disconnected from the bus and entered into an Inactive State. Otherwise, the card will return its VCC range in response.

If the card can operate at the supplied voltage, the response will return the supply voltage and the check mode set in the command parameters. If the card does not work at the voltage supplied, it does not return a response and remains idle. When initializing the SDHC card, it is mandatory to send CMD8 before the ACMD41 command. Receiving CMD8 is to let the card know that the host supports the physical layer 2.00 protocol and the card supports higher version functions.

### 31.6.1.3 Card identification process

The identification process of the card is different for different cards. These cards include MMC, CE-ATA, SD, or SD I/O cards. All types of SD I/O cards are supported, namely, SDIO\_IO\_ONLY, SDIO\_MEM\_ONLY, and SDIO COMBO. The card identification process steps are as follows:

1. Check whether the card is connected.
2. Type of identification card: SD card, MMC (CE-ATA) or SD I/O card.
  - Send a CMD5 command. If the host receives a response, it is the SD I/O card;
  - If no response, send ACMD 41. If the host receives a response, it is the SD card;
  - Otherwise, it is an MMC or CE-ATA device.
3. Initialize the card according to the card type.

Use FOD (400 KHz) as the clock source and send commands in the following order:

- SD card-transmit CMD0, ACMD41, CMD2, CMD3;
- SDHC card-transmit CMD0, CMD8, ACMD41, CMD2, CMD3;
- SD I/O card-if the card has no memory port, send CMD52, CMD0, CMD5, CMD3; Otherwise, transmit CMD52, CMD0, CMD5, ACMD41, CMD11 (optional), CMD2, CMD3;
- MMC/CE-ATA-transmit CMD0, CMD1, CMD2, CMD3.

Identify the MMC/CE-ATA device.

- The CPU should query 504 bytes of the EXT\_CSD register (S\_CMD\_SET) by sending CMD8. If the 4th bit is set to 1, the device supports ATA mode;
  - If ATA mode is supported, the CPU should select ATA mode by setting the (4th bit) ATA bit of the 191 bytes (CMD\_SET) of the EXT\_CSD register to activate the use of the ATA command set. The CPU selects the command set using the SWITCH (CMD6) command;
  - If a CE-ATA device exists, the FAST\_IO (CMD39) and RW\_MULTIPLE\_REGISTER (CMD60) commands will succeed and the data returned will be the CE-ATA reset signature.

### 31.6.2 No data command

When sending any data-less commands, the software needs to set the SDIO\_CMD register and SDIO\_ARG register with the appropriate parameters. Through these two registers, the host forms commands and sends them onto the command bus. The host reflects the error of the command response through the error flag of the SDIO\_STA register.

When the response is received, the host sets the SDIO\_INTSTS register RCRC (response error) bit to 1. The short response is copied to SDIO\_RESP0, while the long response is copied to all four response registers. The 31st bit of the SDIO\_RESP3 register represents the highest bit of the long response, while the 0th bit of the SDIO\_RESP0 register represents the lowest bit of the long response

### 31.6.3 Write data command

The single block or multi-block writing operation steps are as follows:

1. Set the data size (in bytes) in the SDIO\_DLEN register.
2. Set the data block size in the SDIO\_BLKSIZE register; The host sends a BLKSIZE sized block each time.
3. Set the address at which data should be written in the SDIO\_CMDARG register.
4. Set the SDIO\_CMD register. For SD memory cards and MMC cards, use the CMD24 command to write for a single block and the CMD25 command to write for multiple blocks. For SD I/O cards, the CMD53 command is used for single and multi-block transfers. For CEATA, first write the ATA task file with CMD60, and then write the data with CMD61 command. After writing to the CMD register, the host starts executing a command, and when the command is sent to the bus, the CD (Command Complete) flag is set.
5. Write data to SDIO\_FIFO
6. The software should query the data error interrupt. If desired, the software can terminate the data transmission by sending a stop command (CMD12).
7. When a DLEN interrupt is received, the data transfer ends. For open block transfers, if the byte count is 0, the software must send the STOP command. If the byte count is not 0, the host should send a stop command at the end of the given byte count transfer

### 31.6.4 Single block or multiple block reads

The single block or multi-block reading operation steps are as follows:

1. Set the data size (in bytes) in the SDIO\_DLEN register.
2. Set the data block size in the SDIO\_BLKSIZE register; The host sends a BLKSIZE sized block each time.
3. Set the start address where the data needs to be read in the SDIO\_CMDARG register.
4. Set the SDIO\_CMD register. For SD and MMC cards, use CMD17 for single-block reading and CMD18 for multi-block reading. For SD I/O cards, use CMD53 for single-block and multi-block transfers. For CE-ATA, first write the ATA task file with CMD60, and then use CMD61 to read the data. After setting the CMD register, the host starts executing the command, and when the command is sent to the bus, the CD flag is set.
5. The software should query the data error interrupt. If desired, the software can terminate the data transmission by sending a stop command (CMD12).
6. The software should read data from the FIFO and free up space in the FIFO to receive more data.
7. When a DTEND interrupt is received, the software should read out the remaining data in the FIFO.

|------|--------|----|------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 7: 0 | CLKDIV | RW | 8'h0 | CLKDIV: clock frequency division coefficient, defines the frequency division coefficient between the input clock (SDIOCLK) and the output clock (SDIO_CK):<br>SDIO_CK frequency = SDIOCLK/[CLKDIV * 2] |
|------|--------|----|------|--------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

Note:

1 When the SD/SDIO card or MMC is in recognition mode, the frequency of SDIO\_CK must be lower than 400KHz.

2 When all cards are assigned corresponding addresses, the clock frequency can be changed to the maximum frequency allowed by the card bus.

3 This register cannot be written within 7 HCLK clock cycles after data is written. For SD I/O cards, SDIO\_CK may be stopped during read wait, at which time the SDIO\_CLKCR register does not control SDIO\_CK.

### 31.7.3 SDIO parameter register (SDIO\_ARG)

Address offset: 0x08

Reset value: 0x0000 0000

The SDIO\_ARG register contains 32-bit command parameters that will be sent to the card as part of the command.

### 31.7.4 SDIO Command Register (SDIO\_CMD)

Address offset: 0x0C

Reset value: 0x2000 0000

The SDIO\_CMD register contains the command index and command type bits. The command index is sent to the card as part of the command. Command Type Bit Control Command Channel State Machine (CPSM)

| 5: 0 | CMDINDEX         | RW | 6'h0 | Command Index                                                                                                                                                                                                              |

Note: 1: This register cannot be written within 7 HCLK clock cycles after data is written.

2: The MMC can send two kinds of responses: a short response with a length of 48 bits or a long response with a length of 136 bits. SD cards and SD I/O cards can only send short responses, the parameters can vary according to the type of response, and the software will distinguish the type of response according to the command sent. CE-ATA devices send only short responses.

### 31.7.5 SDIO command response register (SDIO\_RESPCMD)

Address offset: 0x10

Reset value: 0x0000 0000

The SDIO\_RESPCMD register contains the command index in the last received command response. If the transmitted command response does not contain the command index (long response or OCR response), the content of the RESPCMD field is unknown, although it should contain 111111b (reserved field value in response).

### 31.7.6 SDIO command response register (SDIO\_RESPX)

Address offset: 0x14 + 4 \* (x-1), where x = 1.. 4

Reset value: 0x0000 0000

The SDIO\_RESP1/2/3/4 register contains the status of the card, i.e. part of the received response.

|                      |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |
|----------------------|----|----|----|----|----|----|----|----|----|----|----|----|----|----|----|
| 31                   | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 20 | 19 | 18 | 17 | 16 |
| CARDSTATUSx [31: 16] |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |
| R                    | R  | R  | R  | R  | R  | R  | R  | R  | R  | R  | R  | R  | R  | R  | R  |

| CARDSTATUSx [15: 0]  |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |
| R                    | R  | R  | R  | R  | R  | R  | R  | R  | R  | R  | R  | R  | R  | R  | R  |

| Bit   | Name        | R/W | Reset Value | Function                     |
|-------|-------------|-----|-------------|------------------------------|
| 31: 0 | CARDSTATUSx | R   | 32'h0       | CARDSTATUSx: See table below |

Depending on the response state, the state length of the card is 32 bits or 127 bits.

Table 31-28 response type and SDIO\_RESPx register

| Register   | Short response      | Long response         |
|------------|---------------------|-----------------------|
| SDIO_RESP1 | Card status [31: 0] | Card Status [127: 96] |
| SDIO_RESP2 | need not            | Card Status [95: 64]  |
| SDIO_RESP3 | need not            | Card Status [63: 32]  |
| SDIO_RESP4 | need not            | Card status [31: 1]   |

The highest bit of the card status is always received first, and the lowest bit of the SDIO\_RESP3 register is always 0.

### 31.7.7 SDIO Data Timer Register (SDIO\_TMOUT)

Address offset: 0x24

Reset value: 0xFFFFFFFF40

The register contains the data timeout in units of card bus clock cycles.

| 31               | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23              | 22 | 21 | 20 | 19 | 18 | 17 | 16 |
|------------------|----|----|----|----|----|----|----|-----------------|----|----|----|----|----|----|----|
| DATETIME [23: 8] |    |    |    |    |    |    |    |                 |    |    |    |    |    |    |    |
| RW               | RW | RW | RW | RW | RW | RW | RW | RW              | RW | RW | RW | RW | RW | RW | RW |
| 15               | 14 | 13 | 12 | 11 | 10 | 9  | 8  | 7               | 6  | 5  | 4  | 3  | 2  | 1  | 0  |
| DATETIME [7: 0]  |    |    |    |    |    |    |    | RESPTIME [7: 0] |    |    |    |    |    |    |    |
| RW               | RW | RW | RW | RW | RW | RW | RW | RW              | RW | RW | RW | RW | RW | RW | RW |

When DPSM is in these states, if the counter decreases to 0, a timeout flag is set.

| Bit   | Name             | R/W | Reset Value | Function                                                                        |
|-------|------------------|-----|-------------|---------------------------------------------------------------------------------|
| 31: 8 | DATETIME [23: 0] | RW  | 24'hFFFFFF  | DATETIME: Data timeout<br>Data timeout in units of card bus clock cycles.       |
| 7: 0  | RESPTIME [7: 0]  | RW  | 8'h40       | RESPTIME: Command timeout time<br>The command timeout in card bus clock cycles. |

Note: The data timer register and the data length register must be written before writing to the data control register for data transfer.

### 31.7.8 SDIO block length register (SDIO\_BLKSIZE)

Address offset: 0x28

Reset value: 0x0000 0200

| 31                 | 30  | 29  | 28  | 27  | 26  | 25  | 24  | 23  | 22  | 21  | 20  | 19  | 18  | 17  | 16  |

### 31.7.9 SDIO data length register (SDIO\_DLEN)

Address offset: 0x2C

Reset value: 0x0000 0200

The SDIO\_DLEN register contains the length of data bytes to be transferred. When the data transfer starts, this value is loaded into the data counter.

| 31 | 30 | 29 | 28 | 27 | 26 | 25 | 24 | 23 | 22 | 21 | 20 | 19 | 18 | 17 | 16 |

|-------|------------|-----|-------------|-------------|
| 31: 0 | DATALENGTH | RW  | 32'h200     | Data length |

Note: For block data transfer, the value in the data length register must be a multiple of the data block length (SDIO\_BLKSIZE). Before writing to the data control register for data transfer, you must first write the data timer register and the data length register.

### 31.7.10 SDIO Control Register (SDIO\_CTRL)

Address offset: 0x30

Reset value: 0x01000000

### 31.7.13 SDIO Interrupt Mask Register (SDIO\_INTMASK)

Address offset: 0x3C

Reset value: 0x0000 0000

At the corresponding position '1', the interrupt mask register determines which state bit interrupt can be generated.

### 31.7.17 SDIO Data FIFO Register (SDIO\_FIFODATA)

Address offset: 0x200

Reset value: 0x0000 0000

A receive and send FIFO is a 32-bit wide read or write set of registers that contains 32 registers on 32 consecutive addresses.

Note: The data fifo register includes sending and receiving fifos, so these 32 addresses should be divided into groups of 16, with sending and receiving 50%. At each time of reading and writing, data of the size of the receiving FIFO or the writing transmitting FIFO is read at most.

## 32. USB OTG full speed (OTG\_FS)

### 32.1 Overview

OTG\_FS is a Dual Role Device (DRD) controller that supports both device and host functionality and is fully compliant with the On-The-Go supplementary standard of the USB 2.0 specification. Additionally, the controller can also be configured in "Host Only" mode or "Device Only" mode, fully compliant with USB 2.0 specifications. In host mode, OTG\_FS supports full-speed (FS, 12 Mb/s) and low-speed (LS, 1.5 Mb/s) transceivers, while in device mode only full-speed (FS, 12 Mb/s) transceivers are supported. OTG\_FS supports both HNP (Host Negotiation Protocol) and SRP (Session Request Protocol). The only external device needed in host mode is a charge pump that provides VBUS.

#### 32.1.1 Main features

The following will introduce the characteristics of OTG\_FS controller from three aspects: general functions, host mode functions and device mode functions.

##### 32.1.1.1 General Features

- Certified by USB-IF, Universal Serial Bus Specification, Revision 2.0 standard
- The OTG protocol defined in the (physical layer of the OTG\_FS controller, i.e. PHY) USB On-The-Go Supplement, Revision 1.3 specification is fully supported.
  - Identification of inserted Class A-B devices (ID lines)
  - Supports Host Negotiation Protocol (HNP) and Session Request Protocol (SRP)
  - In OTG applications, allow the host to turn off VBUS to save power consumption
  - The OTG controller monitors the VBUS level using an internal comparator
  - Host/device roles can be dynamically switched
- You can configure the following roles through software:
  - USB full-speed devices supporting SRP protocol (Class B devices)
  - USB full-speed/low-speed host supporting SRP protocol (Class A device)
  - USB OTG full-speed dual-role device
- SOF signal supporting full-speed communication and keep-active signal supporting low-speed communication
  - The pulse of the SOF can be output to pin
  - The SOF is internally connected to Timer 2 (TIM2)
  - Configurable frame period
  - Configurable end of frame interrupt
- Has power saving functions, such as stopping the system during USB suspension, turning off the digital module clock, and managing PHY and DFIFO power.
- 1.25 KB of dedicated RAM with advanced FIFO control
  - Configure different RAM areas for different FIFOs through software for flexible and effective use of RAM
  - Each FIFO can store multiple data packets
  - Allow dynamic allocation of storage areas
  - It is not limited that the length of the FIFO must be a power of 2 value to allow flexible and

efficient use of RAM

- The maximum data flow of one frame (1 ms) can be guaranteed without the intervention of the system

### 32.1.1. 2 Host mode functions

The OTG\_FS interface has the following main features and requirements in host mode:

- Requires an external charge pump to power the VBUS
- Supports up to 8 host channels, each channel can be dynamically configured for any transmission type
- Built-in hardware scheduling controller:
  - Supports up to 8 interrupt and synchronous transfer requests in a periodic hardware transfer request queue
  - Supports up to 8 control and bulk transfer requests in the aperiodic hardware transfer request queue.
- In order to efficiently use the RAM space, the data RAM area of the USB is divided into a shared receive FIFO, a periodic transmit FIFO, and an aperiodic transmit FIFO.

### 32.1.1. 3 Device mode functionality

The OTG\_FS interface has the following characteristics in device mode:

- 1 two-way control endpoint 0
- 3 IN endpoints for batch, interrupt, or synchronous transfer
- 3 OUT endpoints for batch, interrupt, or synchronous transfer
- Manage a shared receive FIFO and a send OUT FIFO for efficient use of USB data RAM
- Manage up to 4 dedicated sending IN FIFOs (one FIFO for each IN endpoint) to reduce application load
- Software disconnect function is supported.

### 32.1.2 Structural block diagram

Figure 32-1 OTG\_FS structural block diagram

## 32.2 Functional description

### 32.2.1 OTG Full Speed Controller

The USB OTG full speed controller obtains a  $48 \text{ MHz} \pm 0.25\%$  clock from the Reset and Clock Control Module (RCC). This clock is used to drive the 48 MHz control clock of the USB full speed module (12 Mbit/s). This control clock must be enabled before the OTG full speed controller is configured.

The microcontroller core (CPU) accesses the registers of the OTG full speed controller through the AHB peripheral bus, and USB events are managed by a separate USB OTG interrupt control line.

The microcontroller transmits data to the USB controller by writing 32 bits of data to the OTG\_FS dedicated address (PUSH register), which will be automatically stored in the USB configured send FIFO. Each transmitting FIFO is configured with such a PUSH register to serve each IN endpoint (device mode) or OUT channel (host mode).

The microcontroller obtains 32-bit data from the USB bus by reading the dedicated address (POP register) of the OTG\_FS, which will be automatically loaded from the shared receive FIFO. The receive FIFO is located in a total 1.25 Kbyte USB data RAM area. Each OUT endpoint or IN channel is served by such a POP register.

The USB protocol layer is driven by the Serial Interface Engine (SIE) and connected to a USB full/low speed transceiver module supported by the built-in physical layer (PHY).

### 32.2.2 Full Speed OTG PHY (Physical Interface)

The built-in full-speed OTG PHY is controlled by the OTG full-speed controller and sends and receives control and data signals through the full-speed subset of the UTMI + bus (UTMIFS). PHY provides physical layer support for USB communication.

The OTG PHY at full speed includes the following parts:

- Full/low speed transceiver module for use in host and device modes. This module drives sending and receiving directly on a single-ended USB cable.
- Built-in pull-up resistor for ID line is used to distinguish class A/B devices.
- The DP/DM line has built-in pull-up and pull-down resistors, which are controlled by the OTG\_FS controller to meet the needs of current equipment types. In device mode, when an active level appears on the VBUS line (Class B active), the controller enables the pull-up resistor of the DP line to notify the host to access a USB full-speed device. In host mode, the controller enables the pull-down resistors of both DP and DM lines. The pull-up and pull-down resistors can be dynamically switched when the controller switches role types through the Host Negotiation Protocol (HNP).
- ECN circuit for pull-up/pull-down resistors. The DP line has two pull-up resistors that are separately controlled by the OTG\_FS controller, which meets the ECN requirements of the USB 2.0 version (Engineering Change Notice). Supports dynamic adjustment of the pull-up strength of DP lines, which can better resist noise and improve the quality of transmitted and received signals.
- Built-in VBUS detection comparator with hysteresis function is used to detect the active level, A-B session active level and session end level of VBUS. These levels are used to drive the Session Request Protocol (SRP), detect valid session start and end conditions, and continuously detect VBUS line status in USB communication.

- The VBUS pulse circuit is used for charge/discharge operation (weak drive) of the VBUS through the resistor during SRP.

Note: To ensure proper operation of the USB OTG FS module, the frequency of the AHB should be greater than or equal to 30 MHz.

### 32.2.3 OTG Dual Role Device (DRD)

Figure 32-2 A-B Device Connections for OTG\_FS

#### 32.2.3.1 ID signal detection

The roles of the host and device (default) are defined by the status of the ID line. When you plug in the USB, you can determine the ID cable status based on which end of the USB cable is connected to the micro-AB socket.

- If the B end of the USB cable is plugged in and the ID line is floating, the built-in pull-up resistor will detect the high level of the ID line, at which time the controller is in the default device mode. In this mode, the OTG\_FS controller complies with the description of the standard FSM in Section 6.8. 2: OTG Class B Devices of the OTG 1.3 specification, a supplement to the USB 2.0 specification.
- If the A end of the USB cable is plugged in and the ID cable is grounded. At this point, the OTG\_FS controller will execute an ID line state change interrupt (CIDSCHG bit of the OTG\_FS\_GINTSTS register), automatically switch to host mode, and require software to initialize host mode. In this mode, the OTG\_FS controller complies with the description of standard FSMs in Section 6.8. 1: OTG Class A Devices of the OTG 1.3 specification, which supplements the USB 2.0 specification.

#### 32.2.3.2 HNP dual-role device

The HNP enable bit of the USB global configuration register (the HNPCAP bit of the OTG\_FS\_GUSBCFG register) allows the OTG\_FS controller to dynamically switch between a class A host and a class A device, and between a class B host and a class B device through a host negotiation

protocol (HNP). The status of the current device can be synthesized by reading the ID status bit of the OTG global control and status register (CIDSTS bit of the OTG\_FS\_GOTGCTL register) and the current operation mode bit of the global interrupt and status register (CMOD bit of the OTG\_FS\_GINTSTS register).

### 32.2.3.3 SRP dual-role device

The SRP enable bit of the USB global configuration register (the SRPCAP bit of the OTG\_FS\_GUSBCFG register) allows the OTG\_FS controller to turn off VBUS power, saving power for Class A devices. Note: Class A devices need to control the power supply of the management VBUS whether in host mode or device mode.

### 32.2.4 USB device mode

This chapter describes the functionality of the OTG\_FS controller in USB device mode.

The OTG\_FS controller operates in device mode when:

- OTG B Class equipment
  - When the B end of the USB cable is plugged in, the default is OTG Class B device mode
- OTG A Class equipment
  - The OTG Class A device switches to the device role via the HNP protocol
- Class B equipment
  - When the ID line exists, the B end of the USB cable is plugged in, and the HNP bit of the USB global configuration register
- When (HNPCAP bit of OTG\_FS\_GUSBCFG register) is 0 (refer to Section 6.8. 3 of OTG version 1.3)
- As a USB device only
  - The force device mode bit of the USB global configuration register (the FDMOD bit of the OTG\_FS\_GUSBCFG register) of 1 will force the OTG\_FS controller to operate in USB device mode (refer to Section 6.8. 3 of OTG version 1.3). In this case, the status of the ID line is ignored regardless of whether it exists or not.

Figure 32-3 USB is used for peripheral connection only

#### 32.2.4.1 SRP-capable devices

The SRP enable bit of the USB global configuration register (the SRPCAP bit of the OTG\_FS\_GUSBCFG register) allows the OTG\_FS controller to implement the Session Request Protocol (SRP). In this case, the Class A device can stop supplying power to the VBUS while the USB session is suspended.

#### 32.2.4.2 Device Status

##### Power-on state

After the valid level of the Class B device is detected on the VBUS line, the USB device enters the power-on state. The OTG\_FS controller will automatically enable the pull-up resistor on the DP line to inform the host that a full-speed device is connected, and generate a session request interrupt (SRQINT bit of the OTG\_FS\_GINTSTS register) to mark the power-on state.

The host needs to provide a valid VBUS level throughout the USB communication phase. If it is detected that the level on the VBUS line is below the Class B active level (e.g., a power supply disturbance occurs, or the host power is turned off), the OTG\_FS controller will automatically disconnect the USB connection and generate an end-of-session interrupt (SEDET bit of the OTG\_FS\_GOTGINT register), marking the controller to exit the power-on state.

In the power-on state, the OTG\_FS controller expects to receive a reset signal from the host, and other USB operations are invalid. When the reset signal is received, a reset interrupt (USBRST bit of the OTG\_FS\_GINTSTS register) is generated. After the reset is complete, an enumeration interrupt (ENUMDNE bit of the OTG\_FS\_GINTSTS register) is generated, indicating that the OTG\_FS controller has entered the default state.

##### Software disconnect

You can use software to configure the exit power-on state. Setting the software disconnect bit of the device control register (the SDIS bit of the OTG\_FS\_DCTL register) removes the pull-up resistor on the DP line, allowing the host to recognize a device disconnect event even when the USB cable is still connected.

##### Default status

By default, the OTG\_FS controller expects to receive the SET\_ADDRESS command, at which time all other operations are invalid. When a valid SET\_ADDRESS command is received, the application needs to write the relevant address into the device address bit of the device configuration register (the DAD bit of the OTG\_FS\_DCFG register). The OTG\_FS controller enters the address state and is ready to respond to host transmissions to this address.

##### Pending status

The OTG\_FS controller continuously detects activity on the USB cable. After detecting the USB idle state for 3 ms, an early suspension interrupt (ESUSP bit of the OTG\_FS\_GINTSTS register) is generated, and a suspension interrupt (USBSUSP bit of the OTG\_FS\_GINTSTS register) is generated after 3 ms to acknowledge the suspension. The device suspend bit of the device status register (the SUSPSTS bit of the OTG\_FS\_DSTS register) is automatically set and the OTG\_FS controller enters the suspend state.

The device can spontaneously exit the suspended state by setting the remote wake-up signal bit of the device control register (the WKUPINT bit of the OTG\_FS\_DCTL register) and clearing this bit between 1 ms and 15 ms.

When it is detected that the host sends a recovery signal, a recovery interrupt (RWUSIG bit of the OTG\_FS\_GINTSTS register) will be generated, and the suspend bit of the device will be automatically cleared.

### 32.2.4.3 Device endpoint

The OTG\_FS controller supports the following USB endpoints:

#### ■ Control Endpoint 0

- Bidirectional endpoint, used only for processing control information
- For both IN and OUT directions, there is an independent set of registers to control
- Includes a control (OTG\_FS\_DIEPCTL0/OTG\_FS\_DOEPCTL0) register, a transfer configuration (OTG\_FS\_DIEPTSIZ0/OTG\_FS\_DOEPSIZ0) register, and a status interrupt (OTG\_FS\_DIEPINT0/OTG\_FS\_DOEPINT0) register. Certain bits in the control and transfer length registers differ from the registers of other endpoints.

#### ■ 3 IN endpoints

- Each endpoint can be configured for synchronous, bulk, or interrupt transmission
- Each endpoint has a control (OTG\_FS\_DIEPCTLx) register, a transfer configuration (OTG\_FS\_DIEPTSIZx) register, and a status interrupt (OTG\_FS\_DIEPINTx) register
- The device IN endpoint universal interrupt mask register (OTG\_FS\_DIEPMSK) is used to enable/disable any type of endpoint interrupt source for all IN endpoints, including endpoint 0
- Supports an outstanding synchronous IN transmission interrupt (IISOIXFR bit of the OTG\_FS\_GINTSTS register), which occurs when at least one synchronous IN transmission is outstanding IN the current frame. This interrupt occurs along with a periodic frame interrupt (EOPF of the OTG\_FS\_GINTSTS register)

#### ■ 3 OUT endpoints

- Each endpoint can be configured for synchronous, bulk, or interrupt transmission
- Each endpoint has a control (OTG\_FS\_DOEPCTLx) register, a transfer configuration (OTG\_FS\_DOEPSIZx) register, and a status interrupt (OTG\_FS\_DOEPINTx) register
- The device OUT endpoint universal interrupt mask register (OTG\_FS\_DOEPMSK) is used to enable/disable any type of endpoint interrupt source for all OUT endpoints, including endpoint 0
- Supports an outstanding synchronous OUT transmission interrupt (INCOMPIISOOUT bit of the OTG\_FS\_GINTSTS register), which occurs when at least one synchronous OUT transmission is outstanding in the current frame. This interrupt occurs along with a periodic frame interrupt (EOPF of the OTG\_FS\_GINTSTS register)

### Endpoint configuration

- The following configuration of endpoints is achieved by setting the endpoint IN/OUT control register (OTG\_FS\_DIEPCTLx/OTG\_FS\_DOEPCTLx):

- Endpoint enable/disable
- Activate endpoints in the current configuration
- Configure USB transfer type (synchronous, batch, interrupt)
- Configure USB packet length
- Configure the transmit FIFO number associated with the IN endpoint
- Configure the PID packets DATA0/DATA1 expected to be received or sent (valid for bulk and interrupt transmissions only)
- Configure odd/even frames for transactions to be sent or received (only valid for synchronous transmission)
- Optional configuration: Set the NAK bit to respond to the host NAK regardless of the FIFO status
- Optional configuration: Set the STALL bit to respond to STALL for any command sent by the host
- Optional configuration: Set the OUT endpoint to listen (SNOOP) mode, and do not verify CRC for received data

### Endpoint Transport

The device endpoint transfer length register (OTG\_FS\_DIEPTSIZE<sub>x</sub>/OTG\_FS\_DOEPTSIZE<sub>x</sub>) is used to configure the transfer length and read the transfer state. This register must be configured before setting the enable bit of the port control register. Once the endpoint is enabled, the register is in a read-only state, and only the OTG\_FS controller can update the transfer status bit of the register.

- The transmission parameters that need to be configured are as follows:

- Length of a single transfer in bytes
- Number of USB packets completing the entire transmission

### Endpoint Status/Interrupt

The device endpoint interrupt register (OTG\_FS\_DIEPINT<sub>x</sub>/OTG\_FS\_DOEPINT<sub>x</sub>) indicates the event status of the endpoint related to USB and AHB. When the OUT endpoint interrupt bit or IN endpoint interrupt bit of the controller interrupt register (OEPINT bit and IEPINT bit of the OTG\_FS\_GINTSTS register) is set, the application program needs to first read all endpoint interrupt registers of the device (OTG\_FS\_DAIN<sub>T</sub>), determine the endpoint number where the interrupt occurred, and then read the endpoint interrupt register of the device to obtain detailed information of the interrupt. The application must immediately clear the corresponding interrupt bits of the registers to clear the corresponding interrupt bits of the OTG\_FS\_DAIN<sub>T</sub> registers and the OTG\_FS\_GINTSTS registers.

- The device controller provides the following status bits and interrupt events:

- The transmission completion interrupt indicates that the data transmission in both AHB and USB is complete.
- SETUP phase completed (valid for control endpoints only)
- The relevant transmission FIFO is already half empty or fully empty (IN endpoint)
- NAK response sent to host (valid for synchronous IN transmission only)
- When the send FIFO is empty, the host makes an IN request (only valid for bulk IN transmission and interrupt IN transmission)

- The host makes an OUT request when the endpoint is not enabled
- Crosstalk error detected
- The application closed endpoint
- The application sets the endpoint state to NAK (only valid for synchronous IN transmissions)
- Received more than 3 consecutive SETUP packets (valid for control OUT transmission only)
- Timeout error detected (valid for control IN transmission only)
- Synchronous transmission type packets are lost without interruption

### 32.2.5 USB host

This chapter describes the functions of the OTG\_FS controller when operating in USB host mode. The OTG\_FS controller operates in host mode when:

- OTG A Class host
  - The A end of the USB cable is plugged in, and the default is OTG class A host mode
- OTG B Class host
  - The OTG Class B device switches to the host role via the HNP protocol
- Class A equipment
  - When the ID line is present, the A end of the USB cable is plugged in, and the HNP bit of the USB global configuration register is 0
- (HNPCAP bit of OTG\_FS\_GUSBCFG register). At this time, the pull-up resistor on the built-in DP/DM line is automatically active.
- As a host only
  - The force host mode bit of the USB global configuration register (the FHMOD bit of the OTG\_FS\_GUSBCFG register) enables the USB host mode in which the OTG\_FS controller operates. At this time, even if the ID cable on the USB connector exists, it is still invalid. The pull-up resistor on the built-in DP/DM line is automatically active.

Figure 32-4 USB is only used for host connection

### 32.2.5.1 SRP-enabled hosts

The SRP function can be supported by configuring the SRP enable bit of the USB global configuration register (the SRPCAP bit of the OTG\_FS\_GUSBCFG register). When the SRP function is enabled, the host can save power by turning off the power supply of VBUS when the USB session is suspended.

### 32.2.5.2 USB host status

#### Host port power supply

The controller does not provide 5 V power supply to VBUS internally, so an external charge pump needs to be used to power the VBUS line. If 5 V power supply can be provided on the application board, an ordinary power switch can also be used. This external charge pump can be controlled through ordinary I/O ports. When the application program needs to set this common I/O port to power the VBUS line, it also needs to set the power supply bit of the host port control and status register (PPWR bit of the OTG\_FS\_HPRT register).

#### VBUS enabled

During the entire USB communication process, the VBUS line needs to be guaranteed to be at an active level at all times. Any event that causes the level of the VBUS line to drop below the threshold (4.25 V) will cause an OTG interrupt (SEDET bit of the OTG\_FS\_GOTGINT register) triggered by the session abort bit. At this point, the application needs to turn off power to the VBUS and clear the port power level. The overcurrent signal of the charge pump can also be used to prevent electrical damage. Connect this overcurrent signal to the I/O port set as the interrupt input. Once an overcurrent event occurs, the application needs to immediately turn off the power supply of VBUS during the interrupt and clear the port power supply potential.

#### Monitoring of device access by host

If the VBUS line has no active level (4.75 V) at all times, the OTG\_FS controller cannot detect the device plugging in whenever a USB device or Class B device is plugged in.

When the VBUS line is within the active level range, once a Class B device is inserted, the OTG\_FS controller generates a host port interrupt triggered by the device insertion bit (PCDET bit of the OTG\_FS\_HPRT register).

#### Monitoring of device disconnection by host

Disconnecting the inserted device will generate a disconnect interrupt (DISCINT bit of the OTG\_FS\_GINTSTS register) triggered by the device disconnect event.

#### Host enumeration

Once the host detects that a device is plugged in and needs to enter the enumeration process, it sends USB reset and configuration commands to the newly plugged device. Because the inserted device has a pull-up resistor on the DP (full speed device) or DM (low speed device) line, it will cause bus instability. When the bus returns to a stable state again, it will trigger an OTG interrupt (DBCDNE bit of the OTG\_FS\_GOTGINT register) for the end of the rebound, and then the host can send a USB reset command to the device.

The application sends a USB reset signal (single-ended 0) to the USB bus by setting the port reset bit of the host port control and status register (PRST bit of the OTG\_FS\_HPRT register). The application program needs to ensure that the reset signal is maintained between 10ms and 20ms, and clear the port reset bit in time.

Once the USB reset sequence is complete, a host port interrupt (PENCHNG bit of the OTG\_FS\_HPRT register) is generated that is triggered by the port enable/disable change bit. This interrupt notifies the application that it can obtain the speed information of the enumerated device (PSPD bit of the OTG\_FS\_HPRT register) from the host port control and status register, whereupon the host will send a SOF (full speed device) signal or remain active (low speed state). At this time, the host can send a configuration command to the device to complete the device enumeration.

### Host suspended

The application can suspend USB activity by setting the port suspend bits of the host control and status registers (the PSUSP bit of the OTG\_FS\_HPRT register). At this time, the OTG\_FS controller will stop sending the SOF signal and enter the suspended state.

The controller may optionally support the remote device to wake up the host to exit the suspended state. At this time, after the controller detects the remote wake-up signal, it will generate a remote wake-up interrupt (WKUPINT bit of the OTG\_FS\_GINTSTS register), and then, the wake-up bits of the host port control and status register (PRES bit of the OTG\_FS\_HPRT register) will be automatically set, and the controller will automatically send a wake-up signal to the USB bus. The application needs to control the maintenance time of the wake-up signal, and clear the port wake-up bit in time to exit the suspended state and restart sending the SOF signal.

If the host needs to spontaneously exit the suspended state, the application program can set the port wake-up bit. At this time, the wake-up signal will be sent to the USB bus. The application program needs to control the time for which this wake-up signal is maintained and clear the port wake-up bit in time.

### 32.2.5.3 Host channel

The OTG\_FS controller provides 8 host channels, each corresponding to a USB host transfer (USB PIPE). The host does not support initiating more than 8 transmission requests at the same time. If the application has more than eight unprocessed transfer requests, the host controller driver (HCD) must reschedule the channel after the channel is re-valid, that is, after receiving the interrupt of transfer completion and channel abort.

Each channel can be configured as input/output mode or as any periodic/apperiodic transmission type. Each channel has a control register (OTG\_FS\_HCCCHARx), a transfer configuration register (OTG\_FS\_HCTSIZx) and a status/interrupt register (OTG\_FS\_HCINTx) and a corresponding mask register (OTG\_FS\_HCINTMSKx).

#### Host channel control

- The channel control register (OTG\_FS\_HCCCHARx) may provide the following operations:
  - Channel enable/disable
  - Configure transfer speed for connected USB devices: Full/Low

- Configure addresses for connected USB devices
- Configure endpoint numbers for connected USB devices
- Configure transmission direction: input/output
- Configure transmission type: control, batch, interrupt, synchronous
- Configure maximum packet length (MPS)
- Configure odd/even frames for periodic transmission

### Host channel transmission

The application configures the transfer length through the host channel transfer length register (OTG\_FS\_HCTSIZx) and reads back the transfer state. You must configure the transmission length before enabling a transmission channel. Once the channel is enabled, the transfer length register becomes read-only, and only the OTG\_FS controller can update this register with the current transfer state.

- The following transmission parameters can be configured:
  - Transmission length of a single packet in bytes
  - The number of all packets in the entire transmission process
  - Starting data PID

### Host channel status/interrupt

The host channel x interrupt register (OTG\_FS\_HCINTx) indicates the channel's USB and AHB related events. When the host channel interrupt bit of the host controller interrupt register (HCINT bit of the OTG\_FS\_GINTSTS register) is set, the application program needs to first read all channel interrupt registers of the host (OTG\_FS\_HCAINT) to obtain the channel number that generated the host channel interrupt, and then read the host channel x interrupt register (OTG\_FS\_HCINTx) according to the channel number to obtain interrupt information. The application needs to clear the corresponding bits of the host channel x interrupt register (OTG\_FS\_HCINTx) in order to clear the corresponding bits of the OTG\_FS\_HAINT and OTG\_FS\_GINTSTS registers. The interrupt source for each channel can be masked by the OTG\_FS\_HCINTMSKx register.

- The host controller provides the following status queries and interrupts:
  - Transfer completion interrupt, indicating that data transfer has been completed on both the application side (AHB) and USB side.
  - Channel abort due to transfer completion, USB communication error, or application prohibit command
  - The corresponding transmission FIFO is already half empty or fully empty (valid for IN channel only)
  - ACK response received
  - NAK response received
  - Received STALL response
  - USB transfer error caused by CRC error, timeout, bit padding error, or erroneous EOP
  - Crosstalk error
  - Frame overflow
  - Data PID (DATA0/DATA1) flip error

### 32.2.5.4 Host scheduler

The host controller has a built-in hardware scheduler, which is used to spontaneously manage and drive application-initiated transmission requests. At the beginning of each frame, the host will process periodic (synchronous and interrupted transmissions) data transmissions before aperiodic (control and bulk transmissions) data transmissions in order to comply with the high priority guarantee of synchronous and interrupted transmissions of the USB specification.

The host manages the USB transmission channel by request queues (one periodic queue and one aperiodic queue). Each request queue can hold 8 requests, and each request represents an unprocessed transfer made by the application. Each request in the request queue carries the IN/OUT direction, channel number and other information to perform a USB transfer. The order in which USB transaction requests are written in the queue determines the order in which they are executed on the USB bus. At the beginning of each frame, the host will process the periodic request queue first, and then the aperiodic request queue. If, at the end of a frame, there is still an unprocessed synchronization or interrupt transmission request, an incomplete periodic transmission interrupt (IPXFR bit of the OTG\_FS\_GINTSTS register) will be generated.

The management of periodic queues and aperiodic queues is completely done by the OTG\_FS controller. The application can obtain the status information of each request queue through read-only registers.

- The periodic transfer FIFO and queue status register (OTG\_FS\_HPTXSTS) and the aperiodic transfer FIFO and queue status register (OTG\_FS\_GNPTXSTS) include:
  - Number of requests that can also be inserted in periodic and aperiodic queues (up to 8)
  - Periodically (aperiodically) transmit the remaining free space in the FIFO (for OUT transmission)
  - IN/OUT commands, number of host channels, and other status information

Since each request queue can hold up to 8 requests, applications can make the best use of this feature and submit up to 8 periodic transmission requests and 8 aperiodic transmission requests to improve transmission efficiency. For example, for block transmission OUT/IN data, the application can configure to transmit up to 64 (maximum number of bytes per packet) × 8 (maximum number of requests) = 512 bytes of data, achieving the highest data transfer rate for a full-speed device. This data will be automatically scheduled by the host without requiring application insertion management.

- The application initiates a periodic (aperiodic) OUT transmission request to the host scheduler through the following steps:
  - Configure transport parameters for host channels
  - Enable configured channels
  - Read the HPTXSTS bit of the OTG\_FS\_GNPTXSTS register to ensure that the periodic (aperiodic) queue can still hold at least 1 request.
  - The OTG\_FS\_HPTXSTS (OTG\_FS\_GNPTXSTS) register is read to ensure that sufficient space remains in the periodic (aperiodic) transmit FIFO. This step may be omitted if the application submits the transmission request after receiving a periodic (aperiodic) transmission

of the FIFO mid-air or full-air break.

- Data is loaded into the corresponding FIFO (PUSH register). Each channel is configured with a PUSH register. Data will be automatically loaded into the corresponding periodic or aperiodic transmit FIFO according to the EPTYPE bit of the OTG\_FS\_HCCHARx register. When the last 32 bits of data is written to the FIFO, a request will be inserted at the end of the request queue, waiting for scheduled execution.
- The application initiates a periodic (aperiodic) IN transmission request to the host schedule through the following steps:
  - Configure transport parameters for host channels
  - Set the channel enable bit of the host channel control register (the CHENA bit of the OTG\_FS\_HCCHARx register) to enable the configured channel. This operation will insert a transport request at the end of the periodic (aperiodic) request queue and wait for scheduled execution.

### 32.2.6 SOF Trigger

Figure 32-5 SOF Connection

The OTG\_FS controller provides:

- Monitoring, tracking and configuration of SOF
- SOF pulse output

These features are useful for the clock output of audio applications because the audio device needs to be synchronized with the data stream of the PC, or because the host needs to adjust the frame rate according to the needs of the audio device

### 32.2.6.1 Host SOF

In host mode, the number of clocks between two consecutive SOFs (full speed devices) or hold active (low speed devices) can be set by configuring the host frame interval register (OTG\_FS\_HFIR), so the application can use it to control the SOF frame period. An interrupt (SOF bit of the OTG\_FS\_GINTSTS register) may be generated in each frame capital. Both the current frame number and time remain unchanged until the next frame number appears in the host frame number register (OTG\_FS\_HFNUM).

Each SOF frame will generate a SOF pulse signal with a width of 12 system clock cycles. Through the SOFOEN bit of the global control and configuration register, this pulse can be configured to be output on the SOF pin. The SOF pulse is also internally connected to the trigger input of timer 2 (TIM2), so input capture, output comparison, and timer can all be triggered by the SOF pulse.

### 32.2.6.2 Device SOF

In device mode, a frame head interrupt (SOF bit of the OTG\_FS\_GINTSTS register) will be generated each time a SOF is received on the USB cable. The current frame number (FNSOF bit of the OTG\_FS\_DSTS register) may be read from the device status register. At this time, a SOF pulse signal with a width of 12 system clock cycles will be generated. This pulse signal can be output on the SOF pin by enabling the SOF output enable bit of the global control and configuration register (SOFOEN bit of the OTG\_FS\_GCCFG register). The SOF pulse signal is also internally connected to the trigger input of timer 2 (TIM2), at which time input capture, output comparison and timer can all be triggered by the SOF pulse. The periodic frame end interrupt (EOPF bit of the OTG\_FS\_GINTSTS register) is used to inform the application that 80%, 85%, 90%, or 95% of the frame has been completed, depending on the frame interval bit of the device configuration register (PFIVL bit of the OTG\_FS\_DCFG register). This function is used to determine whether all synchronous transmissions in a frame have been completed.

### 32.2.7 Power supply options

The power consumption of the OTG PHY is determined by the following 3 bits of the general controller configuration register:

- PHY supply bit (PWRON bit of OTG\_FS\_GCCFG register)
  - Switch on/off of the PHY full speed transceiver module. Pre-setting is required to allow USB communication.
- Class A VBUS monitoring enable bit (VBUSACEN bit of OTG\_FS\_GCCFG register)
  - Toggle on/off the VBUS comparator for Class A devices. In Class A device mode (USB host), it is necessary to enable
  - Can deserve it.
- Class B VBUS monitoring enable bit (VBUSBCEN bit of OTG\_FS\_GCCFG register)
  - Switch that toggles the VBUS comparator for Class B devices. In Class B device mode (USB device), it is necessary to enable
  - Can deserve it.

When USB has no communication or no USB device connection, suspend USB, which can save power.

- Stop PHY clock (STPPCLK bit of OTG\_FS\_PCGCCTL register)
  - When the stop PHY clock bit of the clock gating control register is set, most of the 48MHz clock internally connected to the OTG full speed controller is turned off by gating. At this time, even though the application still enables the 48MHz input clock, the dynamic power consumption caused by the USB clock will be greatly reduced.
  - Most transceivers will be disabled, but the circuitry for detecting asynchronous reset signals and remote wake-up events will remain at
  - Activation status.
- Gated HCLK (GATEHCLK bit of OTG\_FS\_PCGCCTL register)
  - When the gated HCLK bit of the clock gating register is set, most of the system clock internally connected to the OTG\_FS controller is turned off by the gating circuit. Only the access interface of the register remains valid. At this point, even though the application still enables the system clock, the dynamic power consumption caused by the USB clock will be greatly reduced.
- USB System Stop
  - When the OTG\_FS controller is in the USB suspended state, the application needs to completely shut down all system clock sources to completely reduce all power consumption. Set the PHY clock stop bit first, and then set the Power Supply Control System Module (PWR) to enter the system deep sleep mode, which will stop the USB system.
  - Upon detection of a remote wake-up (as a host) or a wake-up signal from the USB bus (as a device), the OTG\_FS controller will automatically resume system activity and the USB clock.

To reduce power consumption, the USB data FIFO is clocked only when the OTG\_FS controller needs to access the FIFO.

### 32.2.8 USB Data FIFO

The following diagram shows a block diagram of the OTG\_FS controller and the functions of each part.

Figure 32-6 OTG\_FS Controller Block Diagram

BIUS: bus interface unit; AIU: Application Program Interface Unit; PFC: package FIFO controller; MAC: media access controller; WPC: wake-up and power-up controller; PIU: PHY interface unit; SIE: serial interface controller

The USB system plans 1.25 K bytes of dedicated RAM for FIFO management. The packet FIFO controller (PFC) module of the OTG\_FS controller divides this RAM into a sending FIFO area and a receiving FIFO area. The application temporarily caches data into the sending FIFO and waits to be sent, while the data received from the USB bus is temporarily cached in the receiving FIFO and waits to be read by the application. The actual number of FIFOs and how these FIFOs are planned in dedicated RAM are determined by the actual application. For example, IN device mode, each IN endpoint will be configured with a sending FIFO, and the size of these FIFOs can be specified by the software. IN this way, the dedicated RAM can optimally meet the needs of the application.

### 32.2.9 FIFO Structure in Device Mode

Figure 32-7 FIFO address image in device mode and FIFO operation image of AHB

#### 32.2.9.1 Receive FIFO in device mode

In device mode, the FS\_OTG controller uses a separate FIFO to cache data for all OUT endpoints. The received packets are in turn cached in the available space of the RX FIFO. The status of the received data packet (including the OUT endpoint number, byte number, data PID number and validity of the received data) is written by the PFC module before the received data. If there is no space left in the receiving FIFO, the controller will respond to the host with a NACK and generate an interrupt at the corresponding endpoint. The size of the receive FIFO may be configured by the receive FIFO length register (OTG\_FS\_GRXFSIZ).

The architecture of using a single RX FIFO enables USB devices to make more effective use of the entire receiving RAM space.

- All OUT endpoints share the entire RAM space (shared FIFO)
- The OTG\_FS controller can utilize the receive FIFO to the maximum extent in the order in which the host sends OUT data

As long as the receiving FIFO has at least one packet waiting to be fetched by the application, the application will continue to receive the receiving FIFO non-null interrupt (RXFLVL bit of the OTG\_FS\_GINTSTS register). The application program obtains packet information by reading the receive status and eject registers (OTG\_FS\_GRXSTSP), and can obtain packets from the receive FIFO by reading the POP register of the corresponding endpoint.

#### 32.2.9.2 Send FIFO in device mode

The shared FIFO mode is not suitable for IN transmission. Only by knowing the order of host requests IN advance or predicting the processing procedure of the process can all endpoint packets be transmitted to the same sending FIFO IN order. So IN device mode, the controller configures a dedi-

cated FIFO for each IN endpoint. The application program may configure the FIFO length of IN endpoint 0 by aperiodic transfer FIFO length register (OTG\_FS\_GNPTXFSIZ), and configure the FIFO length of IN endpoint x by device IN endpoint transfer FIFO register (OTG\_FS\_DIEPTXFx).

The architecture of the dedicated FIFO is very flexible, which greatly reduces the load of the application. These FIFOs have no request sequence, and there is no need to predict the order of access when the USB host accesses the aperiodic endpoint.

According to the value of the aperiodic transmit FIFO null level bit (TXFELVL bit of the OTG\_FS\_GAHBCFG register) configured in the AHB configuration register, the OTG\_FS controller generates a transmit FIFO null interrupt (NPTXFE bit of the OTG\_FS\_GINTSTS register), indicating that the transmit FIFO corresponding to the IN endpoint is half empty or completely empty. The application first obtains the IN endpoint number to be served by reading the interrupt register of all endpoints of the device (OTG\_FS\_DAIN), then checks whether the FIFO has enough remaining space by reading the sending FIFO status register of the IN endpoint x of the device (OTG\_FS\_DTXFSTSx), and finally transmits data to the sending FIFOx by writing the PUSH register of the corresponding endpoint.

### 32.2.10 FIFO Structure in Host Mode

Figure 32-8 Host Mode FIFO Address Image and FIFO Operation Image of AHB

#### 32.2.10.1 Receive FIFO in Host Mode

In host mode, all periodic and aperiodic transmissions are managed using a receive FIFO, which is used to temporarily store data (received data packets) received from the USB bus but not yet transferred to the system storage area. Packets from any remote IN endpoint are temporarily stored IN the FIFO IN order. The status of the received packet (including the host channel number, byte number, data PID and validity of the received data) is also stored in the FIFO. The application may configure the length of this received FIFO through the received FIFO length register (OTG\_FS\_GRXFSIZ).

The architecture of using a single receiving FIFO enables the USB host to make more effective use of the entire receiving RAM space.

- All configured IN channels share the entire RAM space (shared FIFO)
- The OTG\_FS controller can utilize that receive FIFO to the maximum extent according to the sequence of IN commands sent by the host

The application receives a receive FIFO non-null interrupt as long as the receive FIFO has at least one packet waiting to be fetched by the application. The application program can obtain packet information by reading the receive status and eject registers, and obtain packets from the receiving FIFO by reading the POP register of the corresponding endpoint.

### 32.2.10.2 Send FIFO in Host Mode

In host mode, the controller uses one transmit FIFO to manage all aperiodic (control and block transmission) OUT transmissions and the other transmit FIFO to manage all periodic (sync and interrupt) OUT transmissions. These two FIFOs are used to temporarily store data (transmitted packets) to be transmitted to the USB bus. The length of the periodic (aperiodic) transmission FIFO may be configured by the host periodic (aperiodic) transmission FIFO length register (OTG\_FS\_HPTXFBSIZ/OTG\_FS\_GNPTXFBSIZ).

Two transmitting FIFOs are used because it is necessary to ensure the high priority of periodic transmissions in a USB frame. At the beginning of each frame, the built-in host scheduler processes the periodic request queue first and then the aperiodic request queue.

The use of two sending FIFOs makes it convenient for the USB host to optimize the management of periodic and aperiodic data caches separately.

- All host channels used for periodic (aperiodic) OUT transmissions share the same RAM buffer area (shared FIFO)
- The OTG\_FS controller can maximize the use of periodic (aperiodic) transmission FIFO according to the scheduling of the OUT command by the host software.

According to the value of the periodic transmission FIFO null flag bit (PTXFELVL bit of the OTG\_FS\_GAHBCFG register) configured in the AHB configuration register, the OTG\_FS controller generates a periodic transmission FIFO null interrupt (PTXFE bit of the OTG\_FS\_GINTSTS register) to indicate that the periodic transmission FIFO has been half empty or fully empty. The application needs to read the periodic send FIFO and queue status register (OTG\_FS\_HPTXSTS) first to obtain the information of whether the periodic send FIFO and the periodic request queue have remaining space. Only when both the send FIFO and the request queue have remaining space, the application can write data into the FIFO.

According to the value of the aperiodic transmission FIFO null level bit (TXFELVL bit of the OTG\_FS\_GAHBCFG register) configured in the AHB configuration register, the OTG\_FS controller generates an aperiodic transmission FIFO null interrupt (NPTXFE bit of the OTG\_FS\_GINTSTS register), indicating that the aperiodic transmission FIFO has been half empty or fully empty. The application needs to read the aperiodic send FIFO and queue status register (OTG\_FS\_GNPTXSTS) first to obtain the information of whether there is room left in the aperiodic send FIFO and aperiodic request queue. Only when there is room left in both the send FIFO and the request queue, the application can write data into the FIFO.

### 32.2.11 USB System Performance

By configuring large-capacity RAM buffer area, high-degree-of-freedom FIFO length configuration, 32-bit fast access of AHB PUSH/POP registers, and advanced FIFO control mechanism, the OTG\_FS controller can maximize the utilization of RAM space without worrying about the order of USB data, and the USB system achieves the best performance.

These advantages are as follows:

- Reduced application load, no interference with USB transmission, optimized CPU bandwidth usage
  - When data is efficiently transmitted through the USB system, the application program can prepare a large amount of transmission data in advance.
  - The application gets a lot of time to get data from a single receiving FIFO
- The USB module can keep working at full speed, that is, provide the maximum full speed bandwidth (as much hardware as possible runs automatically and as little software as possible participates).
  - The USB controller manages a large data cache area and can autonomously manage the transmission of data on the USB bus
  - The USB controller manages a large data receiving cache area, which can autonomously receive data from the USB bus and fill the cache area

Since the OTG\_FS controller can use the 1.25 K bytes of RAM buffer very efficiently, and 1.25 K bytes is sufficient for managing the transmitted/received data for a full speed frame, the USB system can provide the maximum full speed data transfer rate within each USB frame (1 ms).

### 32.2.12 OTG\_FS Interrupt

Regardless of whether the OTG\_FS controller operates in device mode or host mode, applications cannot access register banks in the other mode. If the application has illegal access, a pattern mismatch interrupt will be generated and the corresponding bit of the controller interrupt register (the MMIS bit of the OTG\_FS\_GINTSTS register) will be affected. When the controller switches from one mode to another, the register banks in the new mode need to be re-initialized in the same way as during power-on reset.

Figure 32-9 Interrupt Architecture

(1) Please refer to the relevant bits of the controller interrupt register

### 32.3 USBFS registers

The register width is 32 bits.

The application program reads and writes the control and status register (CSR<sub>x</sub>) through the AHB slave interface, thus realizing the control of the OTG\_FS controller. These registers are all 32-bit accessed and 32-bit address aligned. Includes the following register sets:

- Controller Global Register Group
- Host Mode Register Group
- Host Global Register Group
- Host Port CSR Register Group
- Host channel related register group
- Device Mode Register Group
- Device Global Register Group
- Device endpoint dependent register set
- Power supply and clock control register bank
- Data FIFO (DFIFO) access register bank

Only the controller global registers, power supply and clock control registers, data FIFO access registers, and host port control and status registers are valid in both host mode and device mode. Regardless of whether the OTG\_FS controller operates in host mode or device mode, applications cannot access register banks in the other mode. If the application has an illegal access, a pattern mismatch interrupt will be generated and the corresponding bit of the controller interrupt register (the MMIS bit of the OTG\_FS\_GINTSTS register) will be affected. When the controller switches from one mode to another, the register banks in the new mode need to be re-initialized in the same way as during power-on reset.

These peripheral registers must be operated in a word (32-bit) manner.

### **32.3.1 CSR memory image**

The host mode register and the device mode register occupy different addresses. All registers are driven by the AHB clock.

Figure 32-10 CSR memory image

x is 3 in device mode and 7 in host mode

Global CSR address image

These registers are valid in both host mode and device mode.

Table 32-1 controller global control and status registers (CSRs)

| Register code  | Offset address | Register name                        |
|----------------|----------------|--------------------------------------|

Data FIFO (DFIFO) access register address mapping

This set of register columns is valid in both host mode and device mode and is used to read and write the FIFO of a special endpoint or channel in a specified direction. If a channel IN host mode is of type IN, the corresponding FIFO can only perform read operations. Similarly, if a channel in host mode is of OUT type, the corresponding FIFO can only perform write operations.

Table 32-4 Data FIFO (DFIFO) Access Register

| Data FIFO (DFIFO) access register segment                                 | Address range   | Access method |
|---------------------------------------------------------------------------|-----------------|---------------|
| IN endpoint 0 IN device mode/OUT channel 0 IN host mode: DFIFO write only | Write operation | 0x1000~0x1FFC |
| OUT endpoint 0 IN device mode/IN channel 0 IN host mode: DFIFO read only  | Read operation  |               |
| IN endpoint 1 IN device mode/OUT channel 1 IN host mode: DFIFO write only | Write operation | 0x2000~0x2FFC |
| OUT endpoint 1 IN device mode/IN channel 1 IN host mode: DFIFO read only  | Read operation  |               |
| .....                                                                     | .....           | .....         |
| IN endpoint x IN device mode/OUT channel x IN host mode: DFIFO write only | Write operation | 0xX000~0xXFFC |
| OUT endpoint x IN device mode/IN channel x IN host mode: DFIFO read only  | Read operation  |               |

The x in the table is 3 in device mode and 7 in host mode

Power and Clock Control CSR Register Image

There is only one register used to control power supply and clock control, and this register is valid in both device mode and host mode.

Table 32-5 Supply and Gate Control and Status Registers

| Register name                            | abbreviation | Offset address |
|------------------------------------------|--------------|----------------|
| Powered and gated clock control register | PCGCR        | 0xE00~0xE04    |
| Reserved                                 | 0xE05~0xFFFF |                |

## 32.4 OTG\_FS Global Register

These registers are valid in both device mode and host mode, and do not require re-initialization during mode switching. Unless otherwise specified, the value of each of the registers is represented by a binary number.

### 32.4.1 OTG\_FS control and status register (OTG\_FS\_GOTGCTL)

Address: 0x0000

Reset value: 0x0001 0000

| 2:0   | TOTAL [2: 0] | RW   | 3'h0 | <p>TOTAL: FS timeout calibration (FS timeout calibration) Considering the additional delay brought by PHY, the application program can adjust the full-speed packet timeout determination delay of the controller. These bits give the length of the adjustment delay in terms of the number of PHY clocks. Different PHYs bring different additional delays when controlling the bus state, and these bits can adapt to different bus delays. The timeout judgment of full-speed packets specified by the USB standard is 16 to 18 BIT times. The application needs to configure this bit based on the speed of the enumeration. The increased BIT time per PHY clock is 0.25 BIT time.</p> |

| 1      | HSRST         | RS    | 0    | <p>HSRST: The HCLK soft reset application can use this bit to refresh the control logic of the AHB clock domain. Only modules driven by the AHB clock domain are reset. FIFO is not affected by this bit. According to the protocol, all state machines driven by the AHB clock domain will be reset to the idle state after completing the current transmission of the AHB. Clear the CSR control bit in the AHB clock domain driven state machine. To clear this interrupt, the state mask bits used to control the interrupt state and generated by the state machine driven by the AHB clock domain will be cleared. Since the interrupt status bit is not cleared, the application can still obtain the status of any controller events generated after setting this bit. The controller automatically clears this bit after all necessary logic modules are reset. This operation will be maintained for several clock cycles, which are determined by the current state of the controller. Note: Works in both device mode and host mode.</p>         |

|  |  |  |  | <p>register GAYEHCLK bit of OTG_FS_PCGCCTL register PWRCLMP bit of OTG_FS_PCGCCTL register STPPCLK bit of OTG_FS_HCFG register FSLSPCS bit of OTG_FS_HCFG register DSPD bit of OTG_FS_HCFG register All modules state machines (except AHB slave unit) will be reset to idle state, and all send FIFOs and receive FIFOs are flushed. All data transmission on the AHB master module ends immediately after the final data phase of the AHB transmission is completed. All transfers over USB end immediately. The application can set this bit any time it needs to reset the controller. The controller will automatically clear this bit after all necessary logic modules are reset. This operation will be maintained for several clock cycles, depending on the current state of the controller. Once this bit is cleared, the software must wait for at least 3 PHY clock cycles (delay of synchronous operation) before activating the PHY domain. The application must ensure that bit 31 of this register is '1' (i.e., the AHB master is idle) before starting other operations. Generally, it is only necessary to enter a software reset operation during the software development phase and when the PHY select bit is dynamically modified in the USB configuration registers listed above. If the user changes the PHY configuration, the corresponding clock is selected and applied to the PHY domain. Once a new clock is selected, the PHY domain needs to be reset for further operation. Note: Works in both device mode and host mode</p> |

| 7      | GONAKEFF | R     | 0 | GONAKEFF: Global OUT NAK effect indicates the application that the global OUT NAK bit of the device control register (SGONAK bit of the OTG_FS_DCTL register) is active. The application clears this bit by writing the clear global OUT NAK bit of the device control register (the CGONAK bit of the OTG_FS_DCTL register). Note: Only valid in device mode.                                                                                                                                                                                                                                                                                                                     |
| 6      | GINAKEFF | R     | 0 | GINAKEFF: Global IN non-periodic NAK effect (Global IN non-periodic NAK effect) indicates that the setting of the global aperiodic IN NAK bit (SGINAK bit of the OTG_FS_DCTL register) of the device control register has taken effect. That is, the controller has responded to the application's operation of setting the global IN NAK bit. The application clears this bit by clearing the clear global aperiodic IN NAK bit of the device control register (the CGINAK bit of the OTG_FS_DCTL register). This interrupt does not mean that a NAK handshake signal is sent to the USB bus, and the STALL bit has a priority over the NAK bit. Note: Only valid in device mode. |
| 5      | NPTXFE   | R     | 1 | NPTXFE: Non-periodic TxFIFO empty (Non-periodic TxFIFO empty) When the aperiodic FIFO is fully empty or half empty, and at least one request can be written in the aperiodic request queue, the controller will generate this interrupt. The FIFO half-empty or full-empty state depends on the aperiodic transmission of the FIFO null level bit (TXFELVL bit of the OTG_FS_GAHBCFG register) by the controller AHB configuration register. Note: Only valid in host mode.                                                                                                                                                                                                        |
| 4      | RXFLVL   | R     | 0 | RXFLVL: RxFIFO non-empty indicates that at least one packet in the receiving FIFO is waiting to be processed. Note: Works in both device mode and host mode.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                       |
| 3      | SOF      | RC_W1 | 0 | SOF: Start of frame In host mode, the controller sets this bit to indicate that a SOF (full speed device) or hold active (low speed device) signal has been sent to the USB bus. The application must write '1' to this bit to clear this interrupt. In device mode, the controller sets this bit to indicate that a SOF is detected on the USB bus. The ap-                                                                                                                                                                                                                                                                                                                       |

|   |        |       |   |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                            |

|   |        |       |   | plication needs to read the device status register to obtain the frame number. This interrupt occurs only when the controller is at full speed. Note: Works in both device mode and host mode.                                                                                                                                                                                                                                                                                                                                             |
| 2 | OTGINT | R     | 0 | OTGINT: The OTG interrupt controller sets this bit to indicate that an OTG protocol event has occurred. The application must read the OTG interrupt register (OTG_FS_GOTGINT) to obtain the specific information that generated this interrupt. The application must clear this bit by clearing the corresponding bit of the OTG_FS_GOTGINT register. Note: Works in both device mode and host mode                                                                                                                                        |
| 1 | MMIS   | RC_W1 | 0 | MMIS: Mode mismatch interrupt The controller sets this bit when an application attempts to access a register in host mode while the controller is running in device mode. When the controller is running in host mode, it attempts to access registers in device mode. When operating the register, the correct response will be received on the AHB side, but such operations will be ignored internally in the controller and will not have any impact on the operation of the controller. Note: Works in both host mode and device mode |
| 0 | CMOD   | R     | 0 | CMOD: Current mode of operation indicates the current mode. 0: device mode; 1: Host mode. Note: Works in both device mode and host mode                                                                                                                                                                                                                                                                                                                                                                                                    |

### 32.4.7 OTG\_FS Interrupt Mask Register (OTG\_FS\_GINTMSK)

Address: 0x0018

Reset value: 0x0000 0000

This register is used in conjunction with the controller interrupt register to generate interrupts. When an interrupt bit is masked, the corresponding interrupt will not be generated, but the corresponding bit of the controller interrupt register (OTG\_FS\_GINTSTS) will still be set.

### 32.4.8 OTG\_FS Receive Status Debug Read/OTG Status Read and POP Register (OTG\_FS\_GRXSTSR/OTG\_FS\_GRXSTSP)

Read address offset: 0x001C

Ejected address offset: 0x0020

Reset value: 0x0000 0000

A read operation on the receive state debug read register will return the top data in the receive FIFO. A read operation on the receive state debug read register and the POP register will eject the top data item in the receive FIFO. The interpretation of received state data is not the same in host mode and device mode. If the receive FIFO is empty, the controller will ignore the read/POP operation on the receive state and return 0x0000 0000. The application can POP out the receive state FIFO only when the received FIFO non-empty bit of the controller interrupt register (the RXFLVL bit of the OTG\_FS\_GINTSTS register) is '1'.

## 32.5 Registers in host mode

Unless otherwise specified, the values in the registers are expressed in binary form.

Registers in host mode only take effect in host mode and cannot be accessed in device mode. The result of illegal access is undefined

Of. The registers in host mode are as follows:

### 32.5.1 OTG\_FS host mode configuration register (OTG\_FS\_HCFG)

Address: 0x0400

Reset value: 0x0000 0200

This register configures the operation of the controller after power-on. Do not modify this register after initialization.

### 32.5.2 OTG\_FS Host Frame Interval Register (OTG\_FS\_HFIR)

Address: 0x0404

Reset value: 0x0000 EA60

This register sets the frame interval time for the speed selected by the OTG\_FS controller during the enumeration.

### 32.5.4 Primary OTG\_FS host periodically sends FIFO/request queue registers (OTG\_FS\_HPTXSTS)

Address: 0x0410

Reset value: 0x0008 0100

This register is a read-only register, which holds the information of the remaining space of periodically sending FIFO and request queue.

### 32.5.5 OTG\_FS host all channel interrupt register (OTG\_FS\_HAINT)

Address: 0x0414

Reset value: 0x0000 0000

When a signature event occurs on a certain channel, all channel interrupts of the host will interrupt the application program through the host channel interrupt bit of the controller interrupt register (HCINT bit of the OTG\_FS\_GINTSTS register). Each channel has a corresponding channel interrupt bit, with a total of 8 control bits. The application sets and clears this bit by setting and clearing the corresponding bit of the corresponding host channel x interrupt register.

### 32.5.6 OTG\_FS Host All Channel Interrupt Mask Register (OTG\_FS\_HAINTMSK)

Address: 0x0418

Reset value: 0x0000 0000

The host all channel interrupt mask register and the host all channel interrupt register are configured to interrupt the response when an event is generated

Use the program. Each channel has a corresponding interrupt mask bit, with a total of 8 bits.

### 32.5.7 OTG\_FS host port control and status register (OTG\_FS\_HPRT)

Address: 0x0440

Reset value: 0x0000 0000

This register is only valid in host mode. An OTG host controller only supports one port.

This register holds information related to host ports, including USB reset, enable, suspend, wake up, connection status for each port

State and test mode information, etc. The bit designated rc\_w1 can be passed through the host port of the host interrupt register

The interrupt bit (the HPRTINT bit of the OTG\_FS\_GINTSTS register) is used to trigger an interrupt to interrupt the application program. Interrupt service at port

In the service program, the application program must read this register and clear the bit that caused the interrupt. For the bit designated rc\_w1, the application needs

Clear the interrupt by writing '1'.

### 32.5.9 OTG\_FS host channel x interrupt register (OTG\_FS\_HCINTx) (where x represents channel number, x = 0... 7)

Address: 0x0508 + (channel number \* 0x20)

Reset value: 0x0000 0000

This register indicates the status of the channel in relation to the USB and AHB time. When the host channel interrupt bit of the controller interrupt register (HCINT bit of the OTG\_FS\_GINTSTS register) is set, the application program needs to first read all channel interrupt registers of the host (OTG\_FS\_HAINT) to obtain the channel number where the host channel interrupt occurred, and then read the interrupt register of the corresponding channel to obtain detailed information of the interrupt. The application clears the corresponding bits of the OTG\_FS\_HAINT register and the OTG\_FS\_GINTSTS register by clearing the corresponding bits of this register.

### 32.5.10 OTG\_FS host channel x interrupt mask register (OTG\_FS\_HCINTMSKx) (where x is the channel number, x = 0... 7)

Address: 0x050C + (channel number \* 0x20)

Reset value: 0x0000 0000

This register contains the interrupt enable bit of the interrupt flag bit in the USBFS\_HCHxINTF register. If a bit of this register is set by software, the corresponding bit in the USBFS\_HCHxINTF register can trigger a channel interrupt. The bits in this register can be set and cleared by software.

## 32.6 Registers in device mode

### 32.6.1 OTG\_FS device configuration register (OTG\_FS\_DCFG)

Address: 0x0800

Reset value: 0x0820 0000

This register is used to configure the operating characteristics of the controller in device mode after a reset, or special control command, or enumeration. In

Do not modify this register after initialization.

| 1    | SDIS   | RW | 1    | SDIS: Soft disconnect<br>Through this bit, the application tells the OTG controller to perform a software disconnect operation. When this bit is set, the host will see that the device has been disconnected, and the device will not receive any signal from the USB bus. The controller will remain in the OFF state until the program clears this bit.<br>0: Normal operation. When this bit is cleared after the device software is disconnected, the controller will send a device connection event to the host, which will re-execute the enumeration operation.<br>1: The controller performs device software disconnection operation |
| 0    | RWUSIG | RW | 0    | RWUSIG: Remote wakeup signaling<br>When the application sets this bit, the controller will send a remote wake-up signal to wake the USB host. The application must set this bit to exit the controller from the suspended state. According to the USB 2.0 specification, the program must clear this bit again between 1 and 15ms after setting it                                                                                                                                                                                                                                                                                            |

In order for the USB host to recognize the device disconnect operation, the software disconnect (SDIS) bit needs to be held for a period of time. The following table lists

Minimum duration (depending on different states of the device). In order to accommodate the jitter of the clock, it is recommended that the application operate at a defined minimum time

An additional period of delay is reserved.

Table 32-6 Minimum duration of software disconnect

| Operating speed | Device Status                                                  | Minimum duration |
|-----------------|----------------------------------------------------------------|------------------|
| full speed      | Suspend                                                        | 1ms + 2.5 us     |
| full speed      | Idle                                                           | 2.5us            |
| full speed      | Not idle or suspended (transmission operation being performed) | 2.5us            |

### 32.6.4 OTG\_FS Device IN Endpoint Universal Interrupt Mask Register (OTG\_FS\_DIEPMSK)

Address: 0x0810

Reset value: 0x0000 0000

This register cooperates with the device IN endpoint interrupt register (OTG\_FS\_DIEPINTx) to generate the IN endpoint interrupt. The corresponding IN endpoint interrupt corresponding to the OTG\_FS\_DIEPINTx register can be masked by configuring this register. All interrupts are masked by default.

### 32.6.5 OTG\_FS Device OUT Endpoint General Interrupt Mask Register (OTG\_FS\_DOEPMSK)

Address: 0x0814

Reset value: 0x0000 0000

This register is used in conjunction with the device OUT endpoint interrupt register (OTG\_FS\_DOEPINTx) to generate an OUT endpoint interrupt.

Each bit of the OTG\_FS\_DOEPINTx register can be masked by writing the corresponding bit of this register. By default, All interrupts are masked.

### 32.6.6 OTG\_FS device all endpoint interrupt registers (OTG\_FS\_DAIN)

Address: 0x0818

Reset value: 0x0000 0000

When an event occurs at each endpoint, all endpoint interrupt registers of the device pass through the device OUT end of the controller interrupt register respectively

Point interrupt bit or device IN endpoint interrupt bit (OEPINT or IEPINT bit of OTG\_FS\_GINTSTS register) to generate an interrupt

Disconnect the application. Each endpoint has a corresponding bit, the OUT endpoint has 16 bits, and the IN endpoint has 16 bits. For the bidirectional end

Point, using both the IN and OUT bits. The corresponding bit of this register, when the application sets and clears the corresponding device endpoint x interrupts the send

The corresponding bits of the registers (OTG\_FS\_DIEPINTx and OTG\_FS\_DOEPINTx registers) are automatically set and cleared. .

### 32.6.7 OTG\_FS All endpoint interrupt mask register (OTG\_FS\_DAINMSK)

Address: 0x081C

Reset value: 0x0000 0000

The Device All Endpoint Interrupt Mask register is used in conjunction with the Device Endpoint Interrupt register to generate an interrupt to interrupt the application when a device endpoint event occurs. However, the corresponding bits of the device's all endpoint interrupt registers (OTG\_FS\_DAIN) are still set when masked.

### 32.6.12 OTG device endpoint x control register (OTG\_FS\_DIEPCTLx) (where x is the endpoint number, x = 1... 3)

Address: 0x0900 + (x \* 0x20)

Reset value: 0x0000 0000

The application controls the operating characteristics of non-zero endpoints through these registers.

### 32.6.13 OTG\_FS device control OUT endpoint 0 control register (OTG\_FS\_DOEPCTL0)

Address: 0x0B00

Reset value: 0x0000 8000

This section describes the control register for device control OUT endpoint 0. Non-0 control endpoints use the corresponding endpoint 1-3 control registers.

### 32.6.14 OTG\_FS device OUT endpoint x control register (OTG\_FS\_DOEPCTLx) (where x is the endpoint number, x = 1... 3)

Address: 0x0B00 + (x \* 0x20)

Reset value: 0x0000 0000

The application uses this register to control the operating characteristics of endpoints other than endpoint 0

### 32.6.15 OTG\_FS device endpoint x interrupt register (OTG\_FS\_DIEPINTx) (where x is the endpoint number, x = 0... 3)

Address: 0x0908 + (x \* 0x20)

Reset value: 0x0000 0080

This register indicates the event status of the respective endpoint related to USB and AHB. When the IN endpoint interrupt bit of the controller interrupt register (IEPINT bit of the OTG\_FS\_GINTSTS register) is '1', the program must first read all endpoint interrupt registers of the device (OTG\_FS\_DAINTE) to obtain the endpoint number where the event occurred, and then read the interrupt register of the corresponding endpoint to obtain detailed information. The application must clear the corresponding bits of the OTG\_FS\_DAINTE and OTG\_FS\_GINTST registers by clearing this bit.

### 32.6.16 OTG\_FS device endpoint x interrupt register (OTG\_FS\_DOEPINTx) (where x is the endpoint number, x = 0... 3)

Address: 0x0B08 + (x \* 0x20)

Reset value: 0x0000 0000

This register indicates the event status of the respective endpoint related to USB and AHB. When the OUT endpoint interrupt bit of the controller interrupt register (the OEPINT bit of the OTG\_FS\_GINTSTS register) is '1', the application must first read all endpoint interrupt registers of the device (OTG\_FS\_DAINTE) to obtain the endpoint number of the event, and then read the interrupt register of the corresponding endpoint to obtain detailed information. The application must clear the corresponding bits of the OTG\_FS\_DAINTE and OTG\_FS\_GINTST registers by clearing this bit.

### 32.6.17 OTG\_FS Device IN Endpoint 0 Transfer Length Register (OTG\_FS\_DIEPTSIZ0)

Address: 0x0910

Reset value: 0x0000 0000

The application must configure this register before enabling endpoint 0. Once the endpoint of the control register is enabled through the device control endpoint 0

Bit (EPENA bit of the OTG\_FS\_DIEPCTL0 register) enables endpoint 0, and only the controller can modify this register.

The application can only read this register until the endpoint enable bit is cleared.

Non-zero endpoints use registers from endpoint 1 to endpoint 15

### 32.6.18 OTG\_FS Device OUT Endpoint 0 Transfer Length Register (OTG\_FS\_DOEPTSIZ0)

Address: 0x0B10

Reset value: 0x0000 0000

The application must configure this register before enabling endpoint 0. Once endpoint 0 controls the endpoint of the register by device control endpoint 0

When the enable bit (EPENA bit of the OTG\_FS\_DOEPTCTL0 register) is enabled, only the controller can modify this register. control

The application can only read this register until the endpoint enable bit is cleared.

Endpoints other than 0 use registers for endpoint 1 through endpoint 3.

## 33. Ethernet (ENET)

### 33.1 Introduction to Ethernet

Ethernet peripherals can realize Ethernet transmission and data reception according to IEEE 802.3-2002 standard

Ethernet provides configurable, flexible peripherals to meet a variety of applications and customer needs. It supports two industry standard interfaces to the external physical layer: Media Independent Interface (MII) and Reduced Media Independent Interface (RMII) defined in the specification. It can be used in switches, network interface cards and other applications.

Ethernet complies with the following standards:

- IEEE 802.3-2002 standard Ethernet MAC
- Accurate Network Clock Synchronization for IEEE 1588-2002 Standard
- AMBA 2.0 for AHB Master/Slave Port
- RMII specifications as defined by the RMII Association

### 33.2 Ethernet features

Ethernet peripherals include the following features:

- Supports 10/100 Mbit/s data transmission rate via external PHY interface
- IEEE 802.3 compatible MII interface for communication with external Fast Ethernet PHY interface
- Supports full-duplex and half-duplex work
  - Support half-duplex work of CSMA/CD protocol
  - Supports full-duplex operation of IEEE 802.3 x processes
  - In the full duplex operation mode, the received pause control frame can be selectively sent to the user application program
  - Half-duplex operation supporting back pressure flow control
  - When the input flow control signal fails in full duplex mode, the PAUSE frame will be automatically sent
- The preamble and start frame data (SFD) are inserted in the transmitted packet and these fields are deleted in the received packet
- Automatically calculates CRC and generates controllable padding bits on a frame basis
- Automatic removal of padding bits/CRC is optional when receiving a frame
- Programmable frame length to support standard frames up to 16K bytes
- Programmable frame gaps (40 ~ 96 bits, varying in 8 bits)
- Supports multiple flexible address filtering modes
  - Up to 4 48-bit (DA) address filters with a mask per byte
  - Do more than 3 48-bit SA address comparison detection, each byte has a mask
  - 64-bit hash filter for multicast and unicast (DA) addresses
  - Optionally let all multicast address frames pass
  - Promiscuous mode, which supports no filtering during network monitoring, allowing all frames to pass directly
- Returns independent 32-bit status information for packets sent and received

- IEEE 802.1 Q VLAN tags that support detection of received frames
- The application program has independent sending, receiving and controlling interfaces
- Supports mandatory network statistics using RMON/MIB counters (RFC2819/RFC2665)
- Use the MDIO interface to configure and manage PHY
- Detect LAN wake-up frames and AMD's Magic Packet™ frames
- Receiving function: checksum and load shedding of IPv4 and TCP received packets under Ethernet frame framework
- Advanced receive capabilities: IPv4 header checksum and TCP, UDP or ICMP checksum checks in IPv4 and IPv6 datagrams
- Ethernet frame timestamps described in IEEE 1588-2002 are supported. Use a 64-bit timestamp for each frame transmit or receive state
- 2 FIFOs: 2 KB transmit FIFO with programmable depth, 2KB receive FIFO with programmable depth
- The receive state after the EOF is transmitted is inserted into the receive FIFO at the time of receive, and multi-frame storage is enabled in the receive FIFO without requiring another FIFO to store the receive state of these frames
- Optionally filter error frames when received and do not forward them to the application in store-and-forward mode
- Optional forward valid frames with insufficient size
- Supports generating pulses to count the number of frames lost and corrupted (due to overflow) in the received FIFO
- Supports the use of store-and-forward mechanism when sending
- Automatically generate pause frame control or back pressure signal to MAC controller according to FIFO filling level (threshold configurable)
- Handling automatic retransmission of conflicting frames when transmitting
- Drop frames under late collision, over-collision, over-delay, and under-load conditions
- Software Control Empty Send FIFO
- Calculate and insert IPv4 header checksums and TCP, UDP, or ICMP checksums into transport frames in store and forward mode
- Supports internal loopback MII interface for debugging

### **33.2.1 DMA features**

- Under the AHB slave interface, all types of AHB burst transmission are supported
- Under the AHB main interface, the software can select the type of AHB burst transmission (burst of fixed or unfixed length)
- Optional address alignment burst from the AHB master port
- Optimizing packet-oriented DMA transmission using frame delimiters
- Supports byte alignment to address data buffer areas
- Double buffer (ring) and linked list (chain) descriptor list
- Descriptor architecture, allowing large data block transfer with minimal CPU intervention
- Each descriptor can transmit up to 2KB of data

- Comprehensive status reporting for normal operation and error transmission
- Individually programmable burst sizes for sending and receiving DMA, optimizing bus usage
- Programmable interrupt options for different operating conditions
- Interrupt control after transmission/reception of each frame
- Receive and transmit engines two-point loop or fixed priority arbitration
- Start/Stop Mode
- Current Tx/Rx buffer area pointer as status register
- Current Tx/Rx descriptor pointer as status register

### 33.2.2 PTP Characteristics

- Timestamps of received and transmitted frames
- Coarse and fine correction methods
- Trigger interrupt when system time is greater than target time
- Pulse output per second (product replacement function output)

### 33.2.3 CAN block diagram

## 33.3 Description of Ethernet functions: SMI, MII, and RMII

The Ethernet peripheral consists of MAC 802.3 (Media Access Control) and a dedicated DMA controller. Default Media Independent Interface (MII) and Simplified Media Independent Interface (RMII) are supported, both of which can be selected by a 1-bit control bit.

The DMA controller accesses the MAC controller and memory through the AHB master-slave interface. The AHB master interface controls the transfer of data, while the AHB slave interface is used for access control and status register (CSR) space.

Send FIFO (TX FIFO) caches data in system memory through DMA before sending by the MAC controller. Similarly, the receive FIFO (RX FIFO) stores Ethernet frames received from the line until they are transferred to system memory via DMA.

Ethernet peripherals also contain SMI interfaces to communicate with external PHY chips, and users can configure MAC and DMA controllers through a set of configuration registers to select desired operating modes and characteristics.

Note: When using Ethernet, the AHB clock frequency must be greater than or equal to 25Mhz

### 33.3.1 State Management Interface SMI

SMI allows access to PHY registers by implementing the application layer through a 2-wire clock and data line. This interface supports access to up to 32 PHYs. The application layer may select any one of the 32 PHYs and any one of the 32 registers in the PHY to transmit control data and read status signals. Only one register can be addressed in a PHY at any given time

Both the MDC clock line and the MDIO data line are implemented as I/O of the multiplexing function in the MCU

- MDC: A periodic clock provides a time base for data transmission, up to 2.5 MHz. Both the high level and the low level minimum are 160ns, and the period minimum is 400ns. In the idle state, the SMI management interface drives the MDC clock to low.
- MDIO: Data input and output lines, the MDC clock signal synchronously sends status information to or reads from the PHY

#### 33.3.1.1 SMI frame formats

The frame format of read and write operations is as follows:

|   | 帧内容       |     |     |       |       |    |                  |     |
|---|-----------|-----|-----|-------|-------|----|------------------|-----|
|   | 前导符(32 位) | 起始符 | 操作符 | PADDR | RADDR | TA | 数据(16 位)         | 空闲位 |
| 读 | 1...1     | 01  | 10  | ppppp | rrrrr | Z0 | dddddddddddddddd | Z   |
| 写 | 1...1     | 01  | 01  | ppppp | rrrrr | 10 | dddddddddddddddd | Z   |

The management frame consists of the following 8 parts:

- Preamble: Each transmission (read or write) must start with a preamble, which is 32 consecutive logical '1' signals on the MDIO line, and 32 clock signals on the corresponding MDC line. This part of the signal is used to establish synchronization with the PHY device.
- Starter: The starter of the frame is defined as '01', that is, the MDIO line drops from logical '1' to '0' and back to '1' to mark the beginning of the transmission.
- Operator: Used to define the type of operation: read or write.
- PADDR: The address of PHY has 5 bits and can distinguish 32 PHYs. High bits are sent and received first.
- RADDR: The address of the register has 5 bits and can address 32 independent registers. High

bits are sent and received first.

- TA: A 2-digit steering character inserted between RADDR and DATA (DATA) to avoid collisions during read operations. During the read operation, during the 2-bit time of TA, the MAC controller maintains the high impedance state of the MDIO line, while the PHY device maintains the high impedance state of 1 bit first, and outputs a '0' signal at the second bit. During the write operation, during this 2-bit time of TA, the MAC controller drives the MDIO line to output the '10' signal, while the PHY setting remains high impedance.
- DATA: 16 The data field of bits. The first to send and receive is the 15th bit of the ETH\_MIID register.
- Idle bit: The MDIO line remains in a high impedance state. All tri-state drives are cancelled, and the MDIO line is guaranteed to be at logic '1' by the PHY's pull-up resistor.

### 33.3.1.2 SMI write operation

When the application program sets the MW and MB bits (ETH\_MACMIAR), SMI will perform a write operation to the PHY register through the address of the PHY and write the data in the ETH\_MACMIIDR register. The MII address and data register cannot be modified during the operation. Even if they are modified, they will be ignored (the MB bit is always high), and no error will be reported after sending. When the write operation is finished, the SMI interface will clear the MB bits.

### 33.3.1.3 SMI Read Operation

When the MW bit of the ETH\_MACMIAR register is 0, the user sets the MB bit and performs a read operation. The MII address and data register cannot be modified during the operation. Even if they are modified, they will be ignored (the MB bit is always high), and no error will be reported after sending. When the read operation is finished, the MB is pulled low and the MII data register is updated.

### 33.3.1.4 SMI clock selection

The clock of the SMI interface is divided by the application clock (AHB), and the selection of frequency division coefficient depends on the range of the clock. See the bit [5: 2] of the ETH\_MACMIAR register for the specific frequency division coefficient.

### 33.3.2 Independent Media Interface MII

- **MII\_TX\_CLK**: The clock signal used to transmit data. The clock is 2.5 MHz for data transmission of 10 Mbit/s and 25 MHz for data transmission of 100 Mbit/s.
- **MII\_RX\_CLK**: The clock signal used to receive data, the clock is 2.5 MHz for 10 Mbit/s data transmission, and the clock is 25 MHz for 100 Mbit/s data transmission.
- **MII\_TX\_EN**: Send an enable signal, which must be valid when the start bit of the data preamble appears, and needs to remain valid until the transmission is completed.
- **MII\_TXD [3: 0]**: Transmit data line, transmit 4 bits of data at a time, and the data is valid when the MII\_TX\_EN signal is valid. When the MII\_TX\_EN signal is invalid, the PHY will ignore the transmitted data.
- **MII\_CRS**: Carrier sense signal, operating only in half-duplex mode, controlled by PHY. This signal does not need to be synchronized with MII\_TX\_CLK and MII\_RX\_CLK. When it is in an active state, it means that the transmitting or receiving medium is not in an idle state.  
The MII\_CRS signal remains active until both the transmission and reception medium are idle.
- **MII\_COL**: Collision detection signal, operating only in half-duplex mode, controlled by PHY. This signal does not need to be synchronized with MII\_TX\_CLK and MII\_RX\_CLK. This signal is valid when a medium conflict is detected and remains valid for the entire duration of the conflict.
- **MII\_RXD [3: 0]**: Receive data line, receives 4 bits of data each time, and the data is valid when the MII\_RX\_DV signal is valid. Depending on the state of the MII\_RX\_DV and MII\_RX\_ER signals, the MII\_RXD [3: 0] data value may be used to convey some specific information
- **MII\_RX\_DV**: Receive data enable signal, controlled by the PHY, which is active when the PHY

prepares data for the MAC to receive.

- The signal must be valid when the first 4 bits of the data frame appear, and needs to remain valid until the transmission is complete. This signal must become invalid before the first clock after the last 4 bits of data are transferred. To ensure that the frame is received correctly, the MII\_RX\_DV signal should be valid until the SFD field appears.
- MII\_RX\_ER: Received error signal. To indicate that the MAC detected an error during reception, the MII\_RX\_ER signal must remain valid for one or more clock cycles (MII\_RX\_CLK). The specific error reason should be combined with the status of MII\_RX\_DV and the data value of MII\_RXD [3: 0]. See the following table for details: Receiving interface signal encoding

Table 33-1 transmit interface signal encoding

| MII_TX_EN | MII_TXD [3: 0] | Description           |
|-----------|----------------|-----------------------|
| 0         | 0000 to 1111   | Normal frame interval |
| 1         | 0000 to 1111   | Normal data transfer  |

Table 33-2 receive interface signal coding

| MII_RX_DV | MII_RX_ER | MII_RXD      | Description               |
|-----------|-----------|--------------|---------------------------|
| 0         | 0         | 0000 to 1111 | Normal frame interval     |
| 0         | 1         | 0000         | Normal frame interval     |
| 0         | 1         | 0001 to 1101 | Reserved                  |
| 0         | 1         | 1110         | Failed carrier indication |
| 0         | 1         | 1111         | Reserved                  |
| 1         | 0         | 0000 to 1111 | Normal data reception     |
| 1         | 1         | 0000 to 1111 | Data reception error      |

### 33.3.2.1 MII clock scheme

The user needs to provide an external 25MHz clock to the external PHY to generate the TX\_CLK and RX\_CLK clock signals. This clock does not need to be the same as the MAC clock. This clock can be provided using an external 25 MHz crystal oscillator or the clock output pin MCO of the microcontroller. When the clock source is the MCO pin, it is necessary to configure a suitable PLL to ensure that the clock output by the MCO pin is 25 MHz.

### 33.3.3 Simplified Independent Media Interface RMII

The Reduced Media Independent Interface (RMII) specification reduces the number of pins required for Ethernet communication. According to the IEEE 802.3 standard, the MII interface requires 16 pins for data and control signals, while the RMII standard reduces the number of pins to 7.

RMII features:

- Supports 10M and 100Mbit/s rates
- There is only one clock signal, and the clock signal needs to be raised to 50 MHz;
- MAC and external Ethernet PHY need to use the same clock source;
- Use 2-bit width data transmission and reception.

#### 33.3.3.1 RMII clock scheme

Synchronization of both clock sources is ensured by connecting the same clock source to the REF\_CLK pin of the MAC and Ethernet PHY. This clock can be provided via an external 50MHz signal or the MCO pin of the microcontroller. When the clock comes from the MCO pin, a suitable PLL needs to be configured to ensure that the clock output by the MCO pin is 50MHz.

### 33.3.4 MII/RMII selection

The selection of MII and RMII is through bit2 of the offset address 0x0000 register in SYSCFG.

### 33.4 Ethernet function description: MAC 802.3

The IEEE 802.3 Local Area Network (LAN) international standard adopts CSMA/CD (Carrier Sense Multiple Access with Collision Detection) as the access method.

The Ethernet peripheral consists of MAC802.3 controller, media independent interface and DMA controller

The MAC block implements the LAN CSMA/CD sublayer of the following systems: 10 Mbit/s and 100 Mbit/s data rates for baseband and width systems; Full-duplex and half-duplex working modes; The collision detection access mode is only used in half-duplex operation mode; Support MAC control frame sublayer

The MAC sublayer performs the following functions associated with the data link control procedure:

- Data encapsulation (sending and receiving)
  - Generate frames (frame boundary delimitation, frame synchronization)
  - Generate addresses (process source and destination addresses)
  - Error detection
- Media access management
  - Media allocation (collision avoidance)
  - Conflict Resolution (handling conflicts)

The MAC sublayer contains two modes of operation

- Half-duplex mode: sites compete for the right to use physical media through CSMA/CD algorithm
- Full-duplex mode: can send and receive simultaneously without contention resolution when the following states are sent
  - Physical media capabilities to support simultaneous transmission and reception
  - 2 sites connected to LAN
  - 2 sites are configured in full duplex mode simultaneously

#### 33.4.1 MAC 802.3 Frame Format

Two frame formats are defined through CSMA/CDMAC for data transmission:

- Basic MAC frame format
- Label MAC frame format (extension of base MAC frame format)

- Preamble: 7 bytes for synchronization (PLS circuit).  
Hexadecimal value: 55-55-55-55-55-55-55  
Binary: 01010101 01010101 01010101 01010101 01010101 01010101 01010101 (right-to-left transfer)
- Frame Header (SFD): 1 byte, used to indicate the frame head.  
Hexadecimal value: D5  
Binary: 11010101 (right-to-left transfer)
- Destination and Source Addresses: 6 bytes, indicating the destination and source addresses in the following way:
  - Each address is 48 bits.
  - The LSB bit (I/G) of the destination address is used to distinguish between individual addresses (I/G = 0) or group addresses (I/G = 1). A cluster address may point to 0, 1 or more, or all sites in the LAN. The first bit (LSB) bit in the source address is a reserved bit, fixed to '0'
  - The second bit (U/L) of the address is used to distinguish between a single (U/L = 1) address or a global (U/L = 0) address. For broadcast addresses, this bit is fixed to 1.
  - Each byte of the address bit must follow the low-order first transmission rule.  
Address assignments are of the following types:
- Individual address: This is the physical address that points to a specific site in the network.
- Group Address: This is the group address that points to one or more sites in a given network. There are two types of multiple addresses:
  - Multicast Group Address: An address pointing to a group of logically associated sites.
  - Broadcast address: It is a unique, pre-agreed multi-send address (destination address bits are all 1), which always points to all sites in a given LAN.

- QTag Prefix: A 4-byte identifier located between the source address domain and the MAC "Client Length/Type" domain. This identifier belongs to the tagged MAC frame and is an extension of the base frame (untagged). The base frame does not contain this identifier. This identifier includes:
  - The "length/type" field of 2 bytes as a constant, indicating the protocol type (greater than 0x0600), is equal to the value of the 802.1 Q tag protocol type (0x8100). This constant field is used to distinguish labeled and unlabeled MAC frames.
  - A 2 byte field, including control information for the tag. Contains the following parts: 3-bit user priority, 1-bit canonical format indication (CFI), and 12-bit VLAN identifier. The tagged MAC frame has 4 bytes more of the QTag prefix than the base frame.
- MAC client length/type: 2 bytes, which can be divided into two meanings (mutually exclusive) according to their different values:

- If the value of 2 bytes is equal to or less than `maxValidFrame` (1500), then these two bytes represent the number of data field MAC client data bytes (representing length) of the subsequent 802.3 frame.
- If the value of 2 bytes is equal to or greater than `MinTypeValue` (1536 or 0x0600), then these two bytes represent the MAC client protocol type (representative type) associated with the Ethernet frame.

If the length of the data field is less than the minimum receivable length specified by the protocol, the data of the length/type field is ignored, and a padding (PAD) field is added after the data field and before the FCS (Frame Check Sequence) field. When data is transmitted and received in the length/type field, the high order comes first. The protocol does not define how the MAC sublayer handles length/type values between the `maxValidLength` and `minTypeValue` (range disjoint) values. Such data may or may not be received by the MAC sublayer.

- Data and padding fields: `n` bytes of data. The data fields are completely transparent, which means that any sequence of values can appear in the data segment. If there is a padding field, then the length of the padding is determined by the length of the data. The maximum and minimum lengths of the data and padding fields are as follows

- The maximum length is 1500 bytes.
- The minimum length of an unlabeled MAC frame is 46 bytes.
- The minimum length of a labeled MAC frame is 42 bytes.

If the length of the data is less than the minimum length required by the standard (42 bytes for labeled frames and 46 bytes for non-labeled frames), a padding field is added to meet the length required by the standard.

- Frame check sequence: 4 bytes of cyclic redundancy check value (CRC). The CRC calculation includes numerical values for the following fields: source address, destination address, QTag prefix, length/type, LLC data, and padding (i.e. calculates all data except the preamble and SFD fields). Compute the polynomial as follows:

$$G(x) = x^{32} + x^{26} + x^{23} + x^{22} + x^{16} + x^{12} + x^{11} + x^{10} + x^8 + x^7 + x^5 + x^4 + x^2 + x + 1$$

The CRC value of a frame is calculated as follows:

The shortest length of an unlabeled MAC frame is 46 bytes.

- The first two bits of the frame complement each other.
- The `n` bits of the frame serve as coefficients of the polynomial  $M(x)$  of degree  $(n - 1)$ . The first bit of the destination address is used as a coefficient of the  $x^{n-1}$  term, and the last bit of the data field is used as a coefficient of the  $x^0$  term.
- The  $M(x)$  polynomial is multiplied by  $x^{32}$  and divided by  $G(x)$  to produce a remainder  $R(x)$  of degree  $\leq 31$ .
- The coefficients of the  $R(x)$  polynomial are taken as a 32-bit sequence.
- The complement to this sequence is the CRC check value.
- The frame check sequence transmits a 32-bit CRC check value. The coefficients of  $x^{32}$  are

transmitted first, and the coefficients of x0 are transmitted last.

Except for the FCS domain, the sequence of MAC frames is transmitted in low-bit first-out order. A MAC frame is

deemed invalid when:

- The frame length does not match the value defined in the length/type field. If the data of the length/type field is a type value, then the default frame length is consistent with the defined value (no invalid frames).
- The frame length is not an integer multiple of bytes (there are extra bits).
- The CRC value in the FCS domain does not match the CRC value calculated for the actual frame.

### 33.4.2 MAC frame transmission

DMA controls all transactions in the transmission path, by taking Ethernet frames out of system memory and storing them in FIFO. These frames are then sent to the MAC controller. When the EOF (end of frame) is transmitted, indicating the end of the transmission frame, the transmission status is obtained from the MAC controller and transmitted back to the DMA. The depth at which the FIFO is sent is 2 Kbyte. The fill level of the FIFO is indicated to the DMA so that it can use the AHB interface to extract the required burst data from the system memory.

When the SOF is detected, the MAC receives the data and sends it to the MII. The time at which the application layer turns on sending frame data to the MII interface is variable, depending on the delay

like IFG, the time at which the preamble/bounding code is transmitted, and the backoff (forced re-transmission after collision) delay in half-duplex mode. When the EOF is sent to the MAC controller, the controller will complete the regular transmission and then pass the transmission status to the DMA. If a regular collision (in half-duplex mode) occurs during the transmit phase, the MAC controller will make the transmit state valid, and then receive and discard the excess data until the next SOF is received. When a retry request from the MAC is observed, the same frame should be retransmitted from the SOF. If data is not continuously provided during transmission, the MAC issues an underflow state. During normal transmission of a frame, if the MAC receives the SOF without obtaining the EOF of the previous frame, the SOF is ignored and the new frame is considered a continuation of the previous frame.

There are two modes of operation for sending data to the MAC controller:

- **Threshold mode:** When the bytes in the FIFO exceed the configured threshold point (or write the EOF before the threshold is exceeded), the data is ready to be forwarded to the MAC controller. The threshold point may be configured by the TTC bit of the ETH\_DMABMR.
- **Store-and-forward mode:** Only when a complete frame is stored after the FIFO, it will be forwarded to the MAC controller. If the depth of the TX FIFO is less than the length of the transmitted frame, the frame data will also begin to be forwarded to the MAC controller when the FIFO is nearly full
- ◆ **Automatic CRC and byte padding generation**

When the number of bytes received from the application layer is less than 60 (destination address + source address + length/type + data), 0 will be added after the data of the sent frame to ensure that the data length can reach 46 bytes to meet the minimum data length required by IEEE802.3. The MAC can also be configured without increasing the padding domain. The cyclic redundancy check (CRC) of the frame check sequence (FCS) field is calculated and appended to the data being transmitted. When the MAC is configured not to add a CRC value at the end of the frame, the calculated CRC is not transmitted. There is an exception to this rule that if the MAC is configured with additional padding bytes, the CRC will be added at the end of the frame.

- **Send protocol**

MAC controls the working process of sending Ethernet frames:

1. Generate preamble and delimiter
2. Generate blocking 01 sequence in half-duplex mode (jam pattern)
3. Control jabber timer
4. Control flow rate in half-duplex mode (back pressure)
5. Generate transmit frame status
6. Contains timestamp photo logic

When a new frame transmission is requested, the MAC transmits the preamble and delimiter followed by the data. The collision window is defined as 1 gap time (the time corresponding to 512bit), and the blocking mode is only used in the half-duplex mode.

In MII mode, if a collision is sent anywhere in a frame, the MAC sends a 32-bit blocking sequence (0x55555555) to the MII to inform all other stations that a collision has occurred. If the collision occurs

during the transmission of the preamble, the MAC will send the blocking sequence after completing the transmission of the preamble and the delimiter.

The jabber timer is used to cut off the sending process when more than 2048 bytes are sent (default). In half-duplex mode, MAC uses a delay mechanism for traffic control. When the application layer requests to stop receiving frames, as long as traffic control is enabled, it will send a 32-byte blocking sequence when the MAC senses the reception of the frame. This causes a conflict and the remote workstation will fall back. The application requests flow control through the BPA bit of the ETH\_MACFCR register. If the application requests to send a frame, it is scheduled and transmitted even when the activation is pressed. Note that if the backpressure remains active for a long period of time (and more than 16 consecutive collision events occur), the remote station aborts its transmission due to excessive collision. If IEEE 1588 timestamp is enabled for the transmit frame, this block takes a snapshot of system time when the delimiter is placed on the transmit MII bus

#### ■ Send scheduler

The MAC is responsible for scheduling frame transmission on the MII interface. It maintains the gap between two transmitted frames and follows a truncated binary exponential backoff algorithm in half-duplex mode. The MAC starts transmitting after satisfying the IFG and the backoff delay. It remains between two arbitrary transmit frames and configures an idle period (IFG bit in the ETH-MACCR register). If the frame arrives within the IFG time, the MII waits for an enable signal from the MAC before starting transmitting the frame. Once the carrier signal of the MII becomes inactive, the MAC starts its IFG counter. When the value of IFG is configured, the MAC enables transmission in full duplex mode. In the half-duplex mode, when the IFG is configured to correspond to 96 bits, the MAC follows the rules of IEEE 802.3 specification, section 4.2.3.2. 1. If a carrier is detected in the first two-thirds of the IFG interval, the MAC resets the IFG counter. If it is detected in the last third, the MAC will let the IG counter continue to count and enable the transmitter after the IFG interval time has elapsed. MAC implements a truncated binary exponential backoff algorithm in half-duplex mode.

#### ■ Send flow control

When the transmit flow control enable (TFE bit of ETH\_MACFCR) bit is set to 1, in full duplex mode, the MAC generates a pause frame and transmits it. The calculated CRC is appended to the Pause frame and then sent. Pause frame generation can be initiated in two ways: 1. When the FCB position of ETH\_MACFCR is 1 2. When the receive FIFO is full

- If the application layer requests flow control by placing the FCB position 1 of ETH\_MACFCR, the MAC generates and transmits a single pause frame. The value of the pause time in the pause frame is configured by the ETH\_MACFCR register. If the time set in the previously transmitted pause frame is to be delayed or ended, the application layer needs to request the transmission of another pause frame after setting a new pause time value (PT of ETH\_MACFCR).
- If the receiving FIFO is full, the application layer requests flow control, and the MAC will also generate and send a pause frame. If the receive FIFO remains full for the configurable slot time before the pause time is expired, a second pause frame is transmitted. The process repeats as long as the FIFO remains full. If this state is no longer satisfied, the MAC will send a pause frame with zero pause time to indicate

to the remote end that the receiving buffer is ready to receive new data.

#### ■ Single packet sending operation

Regular transmission sequence:

- If the system has data to send, the DMA controller takes them out of memory through the AHB main interface and starts forwarding them to the FIFO. The FIFO continues to receive data until a complete frame is received.
- When the threshold is exceeded or a complete packet is received by the FIFO, the frame data is sent to the MAC controller. The DMA continuously sends data from the FIFO to the MAC. When a frame is transmitted, the DMA controller will receive a status notification from the MAC.

#### ■ Two packet sending operations

- Because the DMA must update the descriptor status before releasing the descriptor to the host, it is possible that up to two frames are sent to the FIFO. Only when the OSF position is 1, the DMA will take out the second frame and put it into the FIFO. If OSF is not set to 1, the next frame is fetched from memory only after the MAC has completely processed one frame and the DMA has released the descriptor
- If OSF position 1, the DMA starts fetching the second frame immediately after completing the transmission of the first frame to the FIFO. It doesn't wait for an update of the status. At the same time, when the first frame is transmitted, the second frame is received by the FIFO. Once the first frame is sent and the MAC returns the status information, it is pushed to the DMA. If the DMA has completed sending the second data packet to the FIFO at this time, the second frame data transmission must wait for the state of the first frame transmission.

#### ■ Retransmission Mechanism in Conflict

In half-duplex mode, when a frame is sent to the MAC, the MAC interface may generate a collision event. The MAC gives a state indicating retransmission even before receiving the end of the frame. Then the retransmission is enabled and the frame is ejected from the FIFO. When more than 96 bytes are forwarded to the MAC controller, the FIFO controller frees up that space and makes it available for DMA to push more data. This means that after transmitting more than 96 bytes or when the MAC controller indicates a delay collision event, it cannot be retransmitted.

#### ■ Send FIFO empty operation

The software flush send FIFO can be performed using bit 20 of the operating mode register. The empty operation is an immediate behavior, even if the Tx FIFO is sending a frame to the MAC controller, it will be affected and the corresponding pointer is reset to the initial position. This causes an underflow event to occur in the MAC transmitter and terminates transmitting the current frame, whose status information will include the underflow and the occurrence of a frame empty event (bit13 and bit1 of TDES0). During the emptying process, DMA will not send data to FIFO. A send status word containing the number of emptied frames is passed to the application. A completely cleared frame will have a frame clearance status position 1 (TDES0). When the application program (DMA) receives all the status words of the clear frame, the clear operation is completed. Send FIFO Clear Control Register Clear.

From this point on, a new frame issued by the application layer is received. After the purge operation, all in-transit data will be discarded unless it starts with SOF.

#### ■ Send Status Word

At the end of the frame sent to the MAC controller and when the controller finishes sending the frame, the sending status is returned to the application. The detailed description of the state is consistent with bit [17: 0] of TDES0. If the IEEE 1588 timestamp is enabled, both the transmit status and the 64-bit timestamp are also returned.

#### ■ Send checksum load shedding

Communication protocols such as TCP and UDP have checksum fields, which can determine the integrity of data transmitted through the network. Because the most widespread use of Ethernet is to encapsulate TCP and UDP through IP fields. Ethernet controller has the feature of sending checksum load shedding, which is used to support checksum calculation and insert it into sending, and can detect errors when receiving. This section describes the checksum load shedding characteristics of the transmitted frame

Note: TCP, UDP, and ICMP checksums are calculated based on the complete frame, and then the calculation results are inserted into the corresponding header area. Based on this characteristic requirement, this function is valid only when the transmit FIFO is configured in a store-and-forward mode (the TSF bit of the ETH\_DMAOMR register is 1). If configured in threshold mode, the transmit checksum load shedding is bypassed.

It is necessary to ensure that the depth of the FIFO can store a complete frame. If the FIFO depth is not sufficient, the checksum insertion function of the payload (TCP/UDP/ICMP) will be bypassed. Even in the store-and-forward mode, only the IPv4 header checksum of the frame can be modified. The transmit checksum load shedding supports two types of checksum calculation and insertion, and the checksum per frame can be controlled by setting the CIC bit (bit28: 27 of the transmit descriptor TDES1)

For IPv4, TCP, UDP, ICMP, IPv6, and ICMPv6 packet header specifications, refer to IETF specifications RFC 791, RFC 793, RFC 768, RFC 792, RFC 2460, and RFC 4443, respectively

#### — IP Header Checksum

In IPv4 fields, the integrity of the header field is represented by the 16-bit header checksum field (eleventh and twelfth bytes of the IPv4 datagram). When the value of the Ethernet frame type is 0x0800 and the IP field version is 0x4, the checksum load shedding detects the IPv4 field. The checksum field of the input frame is ignored during the calculation and replaced by the calculated value. The IPv6 header does not have a checksum field, so checksum load shedding does not modify the IPv6 header field. The result of the IP header checksum calculation is indicated by the IP header error status bit (bit16) in the transmit state, which will be set when the values of the Ethernet frame type field and the IP header version field are inconsistent, or when the Ethernet frame does not have enough data (displayed by the IP header length field). In other words, this bit will be set to 1 when an IP header error is asserted

##### 1. IPv4 Field

- a) The received Ethernet type is 0x0800, but the IP header version field is not equal to 0x4
- b) The IPv4 header length field displays a value less than 0x5 (20 bytes)
- c) The total length of the frame is less than the value of the IPv4 header length field

## 2. IPv6 Field

- a) Ethernet type is 0x86dd, but IP header version field is not equal to 0x6
- b) The frame ends before the IPv6 header (40 bytes) and the extended header (indicated by the corresponding header length field in the extended header) are fully received. If the Ethernet Type field shows a payload for IPv4, it inserts the IPv4 header checksum even if the checksum load shedding detects an IP header error.

## — TCP/UDP/ICMP checksum

The TCP/UDP/ICMP checksum processes IPv4 and IPv6 headers (including extended headers) and determines whether the encapsulated payload is TCP, UDP, or ICMP

Note:

1. For non-TCP/UDP/ICMP/ICMP v6 payloads, the checksum is bypassed and not modified in the frame
2. Segmented IP frames (IPv4 or IPv6), IP frames with security features such as authentication headers or encapsulated security payloads, and IPv6 frames with routing headers are bypassed and not processed by checksums.

The checksum calculates the TCP/UDP/ICMP payload and inserts it into the corresponding field in the header. There are two modes of operation:

1. First mode: TCP, UDP, or ICMP v6 false headers are not included in the checksum calculation and are assumed to be present in the checksum field of the input frame. The checksum field is included in the checksum calculation and is replaced by the final checksum calculation value.
2. The second mode: the checksum field is ignored, TCP, UDP or ICMP v6 false header data is included in the checksum calculation, and the checksum field is overwritten by the final calculated value.

Note that for packets for ICMP-over-IPv4, the checksum field in the ICMP packet must always be equal to 0x0000 in both modes, because there are no fake headers defined in such packets. If it is not equal to 0x0000, an incorrect checksum may be inserted into the packet.

The checksum result is shown by the payload checksum error status bit, at bit 12 of the transmit state vector. Set when sent in any of the following cases:

1. In store-and-forward mode, the frame has begun to be forwarded to the MAC transmitter and the end of the frame is not written to the FIFO
2. In the received IP header, the packet has ended before the byte length corresponding to the payload length field.

When the packet exceeds the byte length corresponding to the payload length field, the byte is ignored as a padding byte, and no error is reported. When the first type of error is detected, the header is not modified. For the second error type, the result of the checksum calculation is still inserted into the corresponding area of the header.

## ■ MII/RMII send bit sequence

Frame transmission in MII and RMII modes:

### 33.4.3 MAC frame reception

The MAC receives the frame and then pushes it into the Rx FIFO. Once the FIFO exceeds the configured reception threshold (RTC bit of the ETH\_DMAOMR register), it will issue a status (padding level) to the DMA. So that the DMA can initiate a preconfigured burst transmission to the AHB interface.

In the default pass-through mode, when 64 bytes (the RTC bit of the ETH\_DMAOMR register) or a complete packet of data is received by the FIFO, the data is ejected and the DMA is notified of its availability. When the DMA has initialized AHB interface transmission, the data will be continuously transmitted from the FIFO until a complete packet is sent. Once the EOF frame has been sent, the status word is ejected and sent to the DMA controller.

In the Rx FIFO store-and-forward mode (the RSF bit of the ETH\_DMAOMR register), the frame can only be read out after it has been fully written into the receiving FIFO. In this mode, all error frames are discarded (if configured), and only valid frames can be read out and forwarded to the application. In the pass-through mode, part of the error frame is not discarded, because the error state is received at the end of the frame, when the beginning of the frame has been read by the FIFO.

When the MAC detects a delimiter on the MII interface, the receive operation is initialized. The MAC controller strips the preamble and delimiter before processing the frame. The header field is checked for filtering and its FCS field is CRC checked. If address filtering fails, the frame is discarded by the controller.

#### ◆ Receiving protocol

Both the preamble and delimiter of the received frame will be stripped. Once the delimiter is detected, the MAC starts sending an Ethernet frame to the Rx FIFO, starting with the byte after the delimiter (destination address). If the IEEE 1588 timestamp is enabled, a photo of the system time is taken when the delimiter is detected. Unless the MAC filters and discards the frame, the timestamp is sent to the application.

If the length/type field of the received frame is less than 0x600, and if the MAC is configured for automatic CRC/PAD. The MAC sends the data of the frame to the Rx FIFO until the count specified in the Length/Type field and then starts dropping bytes (including the delimiter field). If the length/type

field is greater than or equal to 0x600, the NAC sends all received frame data to the Rx FIFO, regardless of whether the automatic CRC function is configured. MAC watchdog is enabled by default, and all parts of frame data greater than 2048 bytes (destination address + source address + length/type + data + padding bytes + frame check sequence) are cut off. This feature is turned off when the watchdog function is turned off. Then even if the watchdog function is turned off, frames larger than 16KB in size will be cut off and a watchdog timeout state will be given.

#### ◆ Receiving CRC: Autofill and CRC stripping

The received frame is checked for CRC errors by the MAC. It calculates the 32-bit CRC, ranging from the destination address to the field portion of the frame check sequence. Encoding Algorithm:

$$G(x) = x^{32} + x^{26} + x^{23} + x^{22} + x^{16} + x^{12} + x^{11} + x^{10} + x^8 + x^7 + x^5 + x^4 + x^2 + x + 1$$

The MAC performs a CRC check calculation on the received full frame, regardless of whether autofill and CRC are stripped.

#### ◆ Receive checksum load shedding

In Ethernet receive frames, both IPv4 and IPv6 frames are detected and processed for data integrity. The reception checksum load shedding may be enabled by setting the IPCO bit of the ETH\_MACCR register. The MAC receiver identifies IPv4 and IPv6 frames by determining whether the value of the frame type field is equal to 0x0800 and 0x86DD. The method can also be used to identify frames with VLAN tags. Received checksum load shedding calculates the IPv4 header and checks if it matches the received IPv4 header checksum. IP header errors are set if the payload type (Ethernet type field) and IP header version do not match, or if the received frame does not have enough bytes, indicated by the length field of the IPv4 header (or when there are fewer than 20 bytes available in the IPv4 or IPv6 header). Received checksum shedding is also used to identify and calculate the checksums of TCP, UDP, and ICMP payloads in IP data segments. It includes TCP/UDP/ICMPv6 pseudo-header bytes for checksum calculation and checks whether the received checksum field matches the calculated value. The match passes the payload checksum error bit in the receive status word

Indicate it. The error bit is also set if the TCP/UDP/ICMP payload length does not match the expected payload length given by the IP header. As mentioned in the TCP/UDP/ICMP verification chapter, receiving checksum load shedding bypasses the payloads of segmented IP datagrams, IP datagrams with security features, IPv6 routing headers, and payloads other than TCP, UDP, or ICMP. This information is reflected in the receive status, as detailed in the RDES0 (Receive Descriptor Word 0) section. In this configuration, the controller does not append any payload checksum bytes to the received Ethernet frame.

| Bit 18:<br>Ethernet frame | Bit 27: Header<br>checksum error | Bit 28: Payload<br>checksum error | Frame status                                                                                                   |
|---------------------------|----------------------------------|-----------------------------------|----------------------------------------------------------------------------------------------------------------|
| 0                         | 0                                | 0                                 | The frame is an IEEE 802.3 frame (Length field value is less than 0x0600).                                     |
| 1                         | 0                                | 0                                 | IPv4/IPv6 Type frame in which no checksum error is detected.                                                   |
| 1                         | 0                                | 1                                 | IPv4/IPv6 Type frame in which a payload checksum error (as described for PCE) is detected.                     |
| 1                         | 1                                | 0                                 | IPv4/IPv6 Type frame in which IP header checksum error (as described for IPCO HCE) is detected.                |
| 1                         | 1                                | 1                                 | IPv4/IPv6 Type frame in which both PCE and IPCO HCE are detected.                                              |
| 0                         | 0                                | 1                                 | IPv4/IPv6 Type frame in which there is no IP HCE and the payload check is bypassed due to unsupported payload. |
| 0                         | 1                                | 1                                 | Type frame which is neither IPv4 or IPv6 (checksum offload bypasses the checksum check completely)             |
| 0                         | 1                                | 0                                 | Reserved                                                                                                       |

#### ◆ Receive frame controller

If the RA bit in the MAC CSR frame filter register is reset, the MAC performs frame filtering based on the destination and source addresses (if the application decides not to receive any bad frames (e.g. runt, CRC error frames, etc.), it still needs to perform another level of filtering.). When a filtering failure is detected, the frame is discarded or sent to the application. When the filter address register is dynamically changed, if the filter fails (DA-SA), the rest of the frame is discarded, and the Rx status word is immediately updated (zero frame length, CRC error, and short error position bits) to show the filter failure. In Ethernet Low Power mode, all frames are discarded and are not forwarded to the application.

#### ◆ Receiving flow control

The MAC detects the reception of the pause frame and pauses the transmission of the frame by the delay time specified in the pause frame (full-duplex mode only). The pause frame detection function may be enabled by the RFCE bit in the ETH\_MACFCR register. When receive flow control is enabled, the destination address of the received frame will always be monitored whether it matches the multicast address of the control frame (0x0180 C200 0001). If a match is detected (the destination address of the received frame matches the destination address of the reserved control frame), MAC will select whether to send the received control frame to the application program through the PCF bit of ETH\_MACFFR.

The MAC will also decode the type of the received control frame, the opcode, the pause timer time, if the byte counter of the state shows 64 bytes, and if there is no CRC error, the MAC transmitter will pause any data transmission within the decoded pause time (pause value multiplied by slot time, 1 slot time = transmission time corresponding to 64 bytes). Meanwhile, if another pause frame is detected and it is a zero pause time, the MAC resets the pause time and manages this new pause request. If the type of the received control frame is not 0x8808, the opcode is not 0x00001, and the byte length is not 64 bytes, the MAC does not generate a pause even if there is no CRC error.

If a pause frame is sent over a multicast destination address, MAC filters the frame by address matching.

If the pause frame is sent over the unicast destination address, MAC will choose to filter the frame based on whether the destination address matches the MAC address0 register and whether the UPDF of ETH\_MACFCR is set to 1 (detecting the pause frame even if it is transmitted over the unicast destination address). The PCF register bit (bit[7: 6] in ETH\_MACFFR) controls filtering of the control frame in addition to address filtering.

#### ◆ Receive Operation Multiframe Processing

Because the status is indicated immediately after the data is sent, the FIFO can store any number of frames as long as it is not full.

#### ◆ Error handling

If the Rx FIFO is full before the end-of-frame data is received from the MAC, an overflow occurs and the entire frame is dropped, and the overflow counter in the ETH\_DMAMFBOCR register is accumulated. Due to overflow, the status indicates that this is a partial frame. If the FEF and FUGF bits of ETH\_DMAOMR are enabled, the Rx FIFO can filter errors and small size frames.

If the receiving FIFO is configured in bit store and forward mode, all error frames are filtered and discarded.

In the pass-through mode, if the state and length of the frame are available when the SOF of the frame is read from the Rx FIFO, the entire error frame can be discarded. DMA can clear erroneous frames read from FIFO by enabling the clear bit of received frames. The data sent to the application is stopped and the rest of the frame is internally read and the MAC interrupt is discarded. You can then start that next frame transmission (if available).

#### ◆ Receive Status Word

At the end of Ethernet frame reception, the MAC outputs the reception status to the application program (DMA). See RDES0 for detailed description of reception status.

#### ◆ Frame length interface

In the case of a switch application, data transmission and reception between the application and the MAC occurs as a complete frame transmission. The application layer should know the length of the frame received from the ingress port in order to transmit the frame to the egress port. The MAC controller places the frame length information in the state at the end of each frame reception.

Note: The frame length value of part of the frames written to the Rx FIFO is 0 due to overflow.

#### ◆ MII/RMII receive bit sequence

Receive the low bit first, then receive the high bit

Received without error:

There is an error when receiving:

There is a false carrier on reception:

### 33.4.4 MAC interrupts

Due to various events, the MAC core may generate interruptions. The ETH\_MACSR register describes when a MAC interrupt is caused. Each event can be prevented from asserting an interrupt by setting a corresponding mask bit in the interrupt mask register.

The interrupt register bit only indicates the set of event reports. The corresponding status register and other registers need to be read to clear the interrupt. For example, bit3 of the interrupt register is set to 1, indicating that a magic packet and a wake-up frame are received in the low power mode. The ETH\_MACPMTCSR register needs to be read to clear the interrupt event.

### 33.4.5 MAC filtering

#### ◆ Address filter

Address filtering checks destination and source addresses in all received frames and reports address filtering status. Address checking is based on different address parameters (frame filter registers) selected by the application layer. Filtered frames can also be identified: multicast or broadcast frames. Address filtering performs address checking through a site's physical address and a multicast hash table.

#### ◆ Unicast destination address filtering

MAC supports unicast perfect filtering for up to 4 MAC addresses, and if perfect filtering is selected (the HU bit of the frame filter register is reset), MAC compares the 48-bit received unicast address to the configured MAC address for a match. The default MAC Addr0 is enabled, and the other addresses MAC Addr1-3 can be controlled by one enable bit, respectively. Each byte of MAC Addr1-3 can be masked for comparison when the destination address is compared, and only the corresponding byte

mask control bit needs to be set. This facilitates group address filtering of destination addresses. In hash filtering mode (HU set), MAC uses a 64-bit hash table to perform imperfect filtering of unicast addresses. For hash filtering, the MAC indexes the contents of the hash table using the upper CRC of 6 bits of the received destination address (see Note 1 below). bit0 in the select hash table register with value 000000 and bit63 in the select hash table register with value 111111. If the corresponding bit (determined by the 6-bit CRC) is set to 1, it means that the unicast frame has passed the hash filtering, otherwise it fails.

Note: CRC is an algorithm for 32-bit values

$$G(x) = x^{32} + x^{26} + x^{23} + x^{22} + x^{16} + x^{12} + x^{11} + x^{10} + x^8 + x^7 + x^5 + x^4 + x^2 + x + 1$$

#### ◆ Multicast destination address filtering

The MAC can pass all multicast frames by configuring the PAM bit in the frame filter register. If the PAM is not set, the MAC will filter the multicast address based on the HM bit. In perfect filtering mode, the address of the multicast frame matches the configured MAC destination address 1-3 register. Group address filtering is also supported. In hash filtering mode, the MAC uses a 64-bit hash table for imperfect filtering. For hash filtering, the MAC indexes the contents of the hash table using the upper CRC of 6 bits of the received destination address (see Note 1 below). bit0 in the select hash table register with value 000000 and bit63 in the select hash table register with value 111111. If the corresponding bit (determined by the 6-bit CRC) is set to 1, it means that the unicast frame has passed the hash filtering, otherwise it fails.

#### ◆ Hash or perfect address filtering

By setting the HPF in the frame filter register, the frame can be considered to have passed when the destination address passes hash filtering or perfect filtering. If HPF = 0, then one type of filtering is supported. Set the corresponding HU and HM bits to realize which filtering mode to select in the filtering of unicast and multicast frames.

#### ◆ Broadcast address filtering

The MAC does not filter broadcast addresses by default, however, if the MAC is configured to refuse to receive broadcast frames through the BFD bit, then all broadcast frames are dropped.

#### ◆ Unicast source address filtering

The MAC also perfectly filters the source address of the received frame. By default, the MAC compares the values of the source address and the source address register. The MAC address registers 1-3 may be configured for source address comparison instead of destination address comparison, which is selected by bit 30 of each register. Group filtering of source addresses is also supported. When SAF position 1 in the frame filtering register, the received frame is discarded if it fails the source address filtering. Otherwise, the result of the source address filtering results in a status bit placed in the receive status word (refer to receive descriptor word 0, RDES0)

When SAD is set to 1, the filtering results of the source address and destination address will be combined with the logic, and then it is decided whether to perform frame forwarding. This means that as

soon as one fails, the frame is discarded. If both addresses are successfully filtered, the frame will be forwarded to the application.

#### ◆ Reverse filtration operation

Filtering for destination and source addresses. One option is to reverse the filtered match result and then output it. This is done by configuring the DAIF and SAIF bits of the frame filter register. The DAIF bit is suitable for the destination address filtering reverse of unicast or multicast frames. SAIF is suitable for source address filtering reverse for unicast frames.

The following figure shows a summary of source address and destination address filtering when different register configurations are configured.

| Frame type | PM | HPF | HU | DAIF | HM | PAM | DB | DA filter operation                                                                  |
|------------|----|-----|----|------|----|-----|----|--------------------------------------------------------------------------------------|
| Broadcast  | 1  | X   | X  | X    | X  | X   | X  | Pass                                                                                 |
|            | 0  | X   | X  | X    | X  | X   | 0  | Pass                                                                                 |
|            | 0  | X   | X  | X    | X  | X   | 1  | Fail                                                                                 |
| Unicast    | 1  | X   | X  | X    | X  | X   | X  | Pass all frames                                                                      |
|            | 0  | X   | 0  | 0    | X  | X   | X  | Pass on perfect/group filter match                                                   |
|            | 0  | X   | 0  | 1    | X  | X   | X  | Fail on perfect/Group filter match                                                   |
|            | 0  | 0   | 1  | 0    | X  | X   | X  | Pass on hash filter match                                                            |
|            | 0  | 0   | 1  | 1    | X  | X   | X  | Fail on hash filter match                                                            |
|            | 0  | 1   | 1  | 0    | X  | X   | X  | Pass on hash or perfect/Group filter match                                           |
|            | 0  | 1   | 1  | 1    | X  | X   | X  | Fail on hash or perfect/Group filter match                                           |
| Multicast  | 1  | X   | X  | X    | X  | X   | X  | Pass all frames                                                                      |
|            | X  | X   | X  | X    | X  | 1   | X  | Pass all frames                                                                      |
|            | 0  | X   | X  | 0    | 0  | 0   | X  | Pass on Perfect/Group filter match and drop PAUSE control frames if PCF = 0x         |
|            | 0  | 0   | X  | 0    | 1  | 0   | X  | Pass on hash filter match and drop PAUSE control frames if PCF = 0x                  |
|            | 0  | 1   | X  | 0    | 1  | 0   | X  | Pass on hash or perfect/Group filter match and drop PAUSE control frames if PCF = 0x |
|            | 0  | X   | X  | 1    | 0  | 0   | X  | Fail on perfect/Group filter match and drop PAUSE control frames if PCF = 0x         |
|            | 0  | 0   | X  | 1    | 1  | 0   | X  | Fail on hash filter match and drop PAUSE control frames if PCF = 0x                  |
|            | 0  | 1   | X  | 1    | 1  | 0   | X  | Fail on hash or perfect/Group filter match and drop PAUSE control frames if PCF = 0x |

| Frame type | PM | SAIF | SAF | SA filter operation                                                        |
|------------|----|------|-----|----------------------------------------------------------------------------|
| Unicast    | 1  | X    | X   | Pass all frames                                                            |
|            | 0  | 0    | 0   | Pass status on perfect/Group filter match but do not drop frames that fail |
|            | 0  | 1    | 0   | Fail status on perfect/group filter match but do not drop frame            |
|            | 0  | 0    | 1   | Pass on perfect/group filter match and drop frames that fail               |
|            | 0  | 1    | 1   | Fail on perfect/group filter match and drop frames that fail               |

### 33.4.6 MAC Loopback Mode

The MAC supports a loopback mode that sends frames to its own receiver. This mode is not enabled by default and can be enabled by the loopback control bit of the ETH\_MACCR register.

### 33.4.7 MAC Management Counter: MMC

The MAC Management Counter (MMC) contains a set of registers to collect statistical information about received and transmitted frames. Includes control registers for controlling register behavior, two 32-bit registers containing generated interrupts, and two 32-bit registers containing corresponding interrupt masks. These registers are accessible through the application layer and are 32 bits wide. When the frame passes the address filtering, the receiving MMC counter will be updated, and the discarded frame statistics will not be updated unless the discarded frame is a short frame less than 6 bytes (DA bytes are not fully received).

#### ◆ Good transmit and receive frames

The transmitted frame is considered good if the transmitter transmits successfully, in other words, if the transmission of the frame is not aborted because of the following errors, it is considered good.

- JABBER timer overflow
- No carrier/carrier loss
- Delay collision
- Short frame
- Excessive delay
- Excessive conflict

The received frame may be considered a good frame if the following error is not transmitted

- CRC error
- Short frames (less than 64 bytes)
- Alignment error (only at 10/100 Mbit, frame is not a full byte at the end)
- Wrong length (atypical frames only)
- Out of range (atypical frames only, over maximum width)
- MII\_RXERinput error

The maximum frame width depends on the frame type:

- Non-labeled frame max size = 1518
- Label frame max size = 1522

### 33.4.8 Power Management: PMT

This section describes the PMT, a power management mechanism supported by MAC. PMT supports receiving wake-up frames and magic packet frames of remote networks. The PMT generates an interrupt when receiving both frames. When the remote wake-up frame is enabled and the magic packet is enabled, the PMT module is enabled with the enable control bits being WFE and MPE in the ETH\_MACPMTCSR register. When entering the low power mode, all received frames are discarded by the MAC and will not be forwarded to the application. Exit low power mode when a wake-up frame or magic packet of the remote network is detected.

#### ◆ Remote wake-up frame filter register

There are eight wake-up frame filter registers, but these registers share the same offset address. When reading or writing to a filter register is completed

, the internal pointer will automatically point to the next filter register. Whether it is a read or write

operation,

it needs to be performed 8 consecutive operations. That is to say, when setting it, the set values need to be divided into 8 times and written to the wake-up frame

filter register address one by one. When reading, it also needs to be read 8 times in a row to read all values.

|            |             |        |        |        |             |        |        |        |
|------------|-------------|--------|--------|--------|-------------|--------|--------|--------|
| 唤醒帧过滤器寄存器0 | 过滤器0字节屏蔽    |        |        |        |             |        |        |        |
| 唤醒帧过滤器寄存器1 | 过滤器1字节屏蔽    |        |        |        |             |        |        |        |
| 唤醒帧过滤器寄存器2 | 过滤器2字节屏蔽    |        |        |        |             |        |        |        |
| 唤醒帧过滤器寄存器3 | 过滤器3字节屏蔽    |        |        |        |             |        |        |        |
| 唤醒帧过滤器寄存器4 | 保留          | 过滤器3命令 | 保留     | 过滤器2命令 | 保留          | 过滤器1命令 | 保留     | 过滤器0命令 |
| 唤醒帧过滤器寄存器5 | 过滤器3偏移      |        | 过滤器2偏移 |        | 过滤器1偏移      |        | 过滤器0偏移 |        |
| 唤醒帧过滤器寄存器6 | 过滤器1 CRC-16 |        |        |        | 过滤器0 CRC-16 |        |        |        |
| 唤醒帧过滤器寄存器7 | 过滤器3 CRC-16 |        |        |        | 过滤器2 CRC-16 |        |        |        |

#### ■ Filter n-byte mask

This register defines which bytes of the frame are used by filter n ( $n = 0, 1, 2, 3$ ) to check whether it is a wake-up frame. Its

31st bit must be '0' and bit [30: 0] is a byte mask bit. If the m-th bit ( $m = 0-30$ ) of filter n ( $n = 0, 1, 2, 3$ ) is '1',

the CRC module that wakes up frame detection processes the [filter n offset + m] byte of the input frame, otherwise ignores it.

#### ■ Filter n command

A total of 4 bits control the working mode of filter n. The highest bit 3 is the address type selection, and if this bit is '1', only multicast frames are detected;

If the bit is '0', only the unicast frame is detected. Bits 2 and 1 must remain 0. Bit 0 is the enable bit of filter n. When set, filter n is enabled, otherwise filter n is disabled.

#### ■ Filter n-offset

Works with filter n-byte mask. This register defines the offset within the frame of the first byte to be checked by filter n. The minimum allowable value

is 12, which represents the 13th byte of the frame (an offset value of 0 represents the 1st byte of the frame).

#### ■ Filter n CRC-16

This register contains a pre-written CRC-16 code for comparison with the CRC-16 value calculated from the frame data.

#### ◆ Remote wake-up frame filtering detection

When the MAC is in a deep sleep state and the remote wake-up bit of the ETH\_MACPMTCSR register is enabled, normal operation resumes after receiving the remote wake-up frame. The application will

write 8 wake-up filter registers, by writing the wake-up frame filter register address 8 times in succession. The application enables the remote wake-up function by writing bit2 of the ETH\_MACPMTCSR register to 1. PMT supports four programmable filters, which provide different patterns of received frame sequences. If the received frame passes address filtering, and if the CRC-16 is consistent with the incoming detection sequence, then the wake-up frame will be received. The filter offset (minimum value 12, representing the 13th byte of the frame) determines the offset of the detected frame. The filtering byte mask determines which byte of the frame must be detected. The 31st bit of the byte mask must be 0. Wake up frames will only check for their length errors, FCS errors, bit loss errors, MII errors, collisions, and need to make sure it is not a short frame. Even if the wake-up frame exceeds 512 bytes in length, the frame is considered valid if it has a valid CRC value. Upon reception of each remote wake-up frame, the detection result of the wake-up frame is updated in the ETH\_MACPMTCSR register. If enabled, an interrupt of the PMT is generated to indicate that a remote wake-up frame has been received.

#### ◆ Magic Package Detection

Another wake-up method is to detect Magic Packet wake-up frames (see AMD's "Magic Packet Technology"). The MAC receives a special packet called a magic packet that addresses network nodes. Only magic packets addressed to a device or broadcast address are checked to determine if they meet the wake-up requirement. Magic packets that pass address filtering (unicast or broadcast) are checked to determine if they conform to the 6-byte remote wake-up LAN data format of all bytes, and then 16 occurrences of the MAC address. Detection is enabled by writing 1 to bit1 of ETH\_MACPMTCSR. The PMT module continuously monitors a frame for a magic packet sequence, checking the 0xFFFF FFFF FFFF sequence of each received frame after the destination and source address fields. The PMT block then checks the frame for 16 repetitions of the MAC address without any interruption or interruption. If an interrupt occurs in 16 repetitions of the address, the 0xFFFF FFFF FFFF sequence is scanned again in the incoming frame. The 16 repetitions can be anywhere in the frame, but must be before the synchronization stream. The device will also receive multicast frames whenever 16 repetitions of the MAC address are detected. For example, if the node address of the MAC is 0x0011 2233 4455, then the MAC will next detect the following data sequence:

```
Destination Address Source Address ... .. FFFF FFFF0011
2233 4455 0011 2233 4455 0011 2233 4455 0011 2233 4455
0011 2233 44550011 2233 4455 0011 2233 4455 0011 2233 4455
0011 2233 4455 0011 2233 44550011 2233 4455 0011 2233 4455 0011
2233 4455 0011 2233 4455 0011 2233 4455 0011 2233 4455 0011 2233 4455 0011
2233
... CRC
```

When a magic packet is received, the detection result of the magic packet is updated in ETH\_MACPMTCSR, and if enabled, a PMT interrupt is generated to indicate that the magic packet has been received.

#### ■ System considerations during low power consumption

When the MCU is in deep sleep mode, if the external interrupt line 19 is enabled, the PMT module of Ethernet can still detect the frame.

The state machine of the MAC receiver needs to remain enabled at all times in low power mode, which means that the RE bit of the ETH\_MACCR register must always be set because it involves the detection of magic packets/wake-up frames. However, during low power mode, the transmit state machines should be turned off by clearing the TE bit in the ETH\_MACCR register. And the DMA also needs to be turned off because there is no need to send the data of the magic packet/wake-up frame to the SRAM. In order to turn DMA off, the ST and SR bits in the ETH\_DMAOMR register need to be reset.

The recommended steps to enter low power and wake up are as follows:

1. Turn off the transmission DMA and wait for the complete transmission of the previous frame, which can be judged by bit [0] of ETH\_DMASR;
2. Turning off the MAC transmitter and receiver by clearing the RE and TE bits in the ETH\_MACCR register;
3. Waiting for the receive DMA to read out all frames in the Rx FIFO, and then turning off the receive DMA;
4. Configuration enables the external interrupt line 19 to generate an event or an interrupt. If the external interrupt line 19 is configured to generate an interrupt, it is also necessary to write an interrupt handler ETH\_WKUP\_IRQ to clear the interrupt flag bit of the external interrupt line 19;
5. Setting the MFE/WFE bit in the ETH\_MACPMTCSR enables detection of the magic packet/wake-up frame;
6. Setting the PD bit in ETH\_MACPMTCSR enables entry into the MAC low power mode;
7. Setting the RE bit in ETH\_MACCR enables the MAC receiver;
8. Enter system STOP mode;
9. When a valid wake-up frame is received, the Ethernet peripheral exits the low power mode;
10. Read ETH\_MACPMTCSR to clear the power management event criteria, enable the MAC send state machine, and enable receive and send DMA;
11. Configure System Clock: Enable HSE and set the clock.

#### 33.4.9 Precise Time Protocol (IEEE1588 PTP)

The IEEE 1588 standard defines a protocol that allows accurate clock synchronization to be used in measurement and system control when using technologies such as network communications, local computing, and distributed objects. The protocol is suitable for systems that communicate over a local area network that supports multicast information, including (but not limited to) Ethernet. The protocol is used to synchronize heterogeneous systems, including clocks with different intrinsic accuracy, resolution, and stability. This protocol supports system-wide synchronization accuracy in the sub-microsecond range, with minimal network and local clock calculation data. Such message-based protocols are called time precision protocols. Systems and networks are classified as master and slave nodes for distributing timing/clock information. The technique of synchronizing master and slave nodes by exchanging PTP information is as follows:

1. The master node broadcasts the PTP synchronization message to all nodes. The synchronization message contains the time information of the master device. When the message leaves the master system, the time is  $t_1$ . In the Ethernet port, this time can be captured by MII.
2. Receiving the synchronization message from the device will also capture the precise time,  $t_2$ , through its time reference
3. The master device then sends a Follow\_up message, which contains  $t_1$  information for later use
4. The slave device sends the Delay\_Req information to the master device, and records the exact time  $t_3$  when the frame leaves the MII
5. When the information enters the system, the master receives the message and captures the exact time  $t_4$
6. The master device sends a Delay\_Resp message containing  $t_4$  information to the slave device
7. The slave device synchronizes its local time reference to the time reference of the master device by four time values  $t_1, t_2, t_3$  and  $t_4$

The protocol is mostly implemented in software above the UDP layer, and then, as described above, hardware support is required to capture the exact time of a particular PTP packet as it enters and leaves the MII interface. This time information must be captured and returned to the software in order to implement PTP correctly and with high precision

#### 33.4.9.1 Reference clock source

To get a snapshot of time, the controller requires a reference time in 64-bit format defined in the IEEE 1588 specification (divided into 2 32-bit channels, with the upper 32 bits providing time in seconds and the lower 32 bits indicating time in ns). The PTP reference clock input is used to internally generate

a reference time (also referred to as system time) and to capture the timestamp. The frequency of the reference clock must be greater than or equal to the resolution of the timestamp counter. The synchronization accuracy between master node and slave node is targeted to be 100ns

The generation, update and modification of system time are described in the next section

The accuracy depends on the input period of the PTP reference clock, the characteristics of the OSC, and the frequency of the synchronization process.

Due to the synchronization from the Tx and Rx clock input domains to the PTP reference clock domain, the uncertainty value of the timestamp is latched to 1 reference clock cycle. If we count the uncertainty value of the resolution, we will add half the cycle time of the timestamp

#### **33.4.9.2 Transmit frame with PTP characteristic**

When the MII interface outputs the SFD of the frame, a timestamp is captured. The frames that need to be captured timestamps are controllable. In other words, each transmit frame may be marked to indicate whether a timestamp necessarily needs to be captured. The transmit frame is not processed to identify the PTP frame. Control of the frame is performed by transmitting control bits in the descriptor. The captured timestamp will be returned to the application in the same way as the frame served state. The timestamp is sent back into the transmit descriptor of the response along with the transmit status of the frame, thereby automatically connecting the timestamp into a particular PTP frame. The 64-bit timestamp information is written back into TDES2 and TDES3, where TDES2 holds the low 32-bit significant bits of the timestamp

#### **33.4.9.3 Receive frame with PTP characteristic**

When the IEEE 1588 timestamp feature is enabled, the Ethernet MAC captures the timestamps of all frames received from the MII. When the frame is received, the MAC provides a timestamp. The captured timestamp will be returned to the application in the same way as the frame served state. The timestamp is sent back into the reception descriptor of the response along with the reception status of the frame. The 64-bit timestamp information is written back into RDES2 and RDES3, where RDES2 holds the low 32-bit significant bits of the timestamp

#### **33.4.9.4 System time correction method**

The 64-bit PTP time is updated by the PTP input reference clock (HCLK). The PTP time is used as a photographed (timestamp) source for MII receive and transmit frames. The system time count may be initialized or corrected by coarse or fine calibration

In the coarse correction method, the initialization value or the offset value is written to the timestamp update register. For initialization, the value of the system time counter is written in the timestamp update register. For system time correction, the offset value is added or subtracted from the system time. In the fine correction method, the frequency drift of the slave device clock (reference clock) from the master device is corrected for a period of time. Unlike the coarse correction method, this correction method is not done in a single cycle. The longer correction time helps to maintain linear time and does not bring drastic jitter (or large jitter) to the reference time between PTP synchronization information intervals. In this method, an accumulator will accumulate the values in the ADDend register as shown

in the figure below, and the arithmetic result generated by the accumulator will be used as the increment pulse of the system time counter. The accumulator and ADDend are both 32-bit registers. Here, the accumulator acts as a high-precision frequency multiplier and divider.

The system time update logic requires a clock frequency of 50Mhz to achieve an accuracy of 20ns, and the frequency division is the ratio of the required clocks in the reference clock domain. Therefore, if the reference clock (HCLK) is 66 Mhz, then the ratio is 66 Mhz/50 Mhz = 1.32. Therefore. The default addend value should be set to  $2^{32}/1.32 = 0xC1F0\ 7C1$

If the reference clock offset is smaller, if 65 Mhz, then the ratio 65/50 = 1.3, and the value in the add register is set to  $2^{32}/1.3 = 0xC\ 4EC\ 4EC\ 4$ . If the clock offset is larger, if it is 67Mhz, the value in the add register should be set to 0xBF0 B7672. If the offset is 0, the default value of add should still be set to 0xC1F0 7C1 ( $2^{32}/1.32$ )

In the figure above, the constant value used to increment the Subsecond register is 0d43. This gives the system time an accuracy of 20ns (in other words, it is incremented in 20ns steps).

The software needs to calculate the offset of the frequency by synchronizing the message and then update the Addend register. Initially, set the slave device clock to a frequency uncompensated value in Addend, which value =  $2^{32}/\text{frequency division}$

If the master-to-slave delay is assumed to be the same for successive synchronization messages, then the algorithm described below needs to be applied. After several synchronization cycles, the frequency values are locked. The slave device clock can determine the delay value of a master device to a slave device and use the new value to resynchronize with the master device.

The algorithm is as follows:

- At MasterSyncTime, the master device sends a synchronization message to the slave device. When the message is received from the device, whether the local clock or SlaveClockTime is calculated  $\text{MasterClockTime} = \text{MasterSyncTime}(n) + \text{MasterToSlaveDelay}(n)$
- Master device clock counts current synchronization period,  $\text{MasterClockCount} = \text{MasterClockTime}(n) - \text{MasterClockTime}(n-1)$  (assuming MasterToSlaveDelay) is the same as synchronization periods n and n-1)

- Count the current synchronization period from the device ,  $\text{SlaveClockCount}(n) = \text{SlaveClockTime}(n) - \text{SlaveClockTime}(n-1)$
- The difference between the master and slave clock count values for the current synchronization cycle is  $\text{ClockDiffCount}(n) = \text{MasterClockCount}(n) - \text{SlaveClockCount}(n)$
- Frequency scale factor of slave device clock  $\text{FreqScaleFactor}(n) = (\text{MasterClockCount}(n) + \text{ClockDiffCount}(n)) / \text{SlaveClockCount}(n)$
- Then the frequency compensation value of the Addend register  $\text{FreqCompensationValue}(n) = \text{FreqScaleFactor}(n) \times \text{FreqCompensationValue}(n-1)$

Theoretically, the algorithm realizes locking in a synchronization cycle; However, it may be delayed by several cycles due to network propagation delays and variations in operating conditions.

The algorithm is self-tuning: if the slave device clock is initially set to an incorrect value compared to the master device, the algorithm will correct it at the expense of more synchronization cycles.

#### 33.4.9.5 Programming steps to initialize the generation system time

The timestamp feature can be enabled by configuring bit0 of the ETH\_PTPTSCR register. After setting this bit, the timestamp counter needs to be initialized. Suitable steps are as follows:

1. Set bit9 of the MACIMR register to mask timestamp-triggered interrupts;
2. Enable timestamp;
3. Calculating the value based on the clock frequency of the PTP, and then configuring the sub-second accumulation register;
4. If using the fine correction method, configure the addend register of the timestamp and configure bit5 of the timestamp control register (addend register update);
5. Polling the timestamp control register until bit5 is cleared;
6. Setting the bit1 selection fine correction method of the timestamp control register;
7. Set the bit2 of the timestamp control register (timestamp time initialization);
8. The timestamp counter starts working after initialization
9. Enable MAC receivers and transmitters

Note: When the bit0 of ETH\_PTPTSCR is cleared to close the timestamp operation, the above operation needs to be restarted again.

#### 33.4.9.6 Updating step of system time in coarse adjustment correction method

1. Write offset values (positive or negative) in timestamp update high and low registers
2. Set timestamp control register bit3 (TSSTU)
3. When the TSSTU bit is cleared, the value in the timestamp update register is added or subtracted from the system time

#### 33.4.9.7 Update step of system time in fine adjustment correction method

1. Using the algorithm introduced in the aforementioned "System Time Calibration Method", the value of the addender register corresponding to the desired system clock frequency is calculated;
2. Update Timestamp
3. Waiting for the desired new value in the add register to take effect, may be by triggering a timestamp interrupt when the system reaches the target value;

4. Configure the required time in the target time high register and low register to unmask the timestamp interrupt by clearing bit9 in the ETH\_MACIMR register;
5. Set the bit4 of the timestamp control register (TSARU);
6. When an interrupt is triggered, read the ETH\_MACSR register;
7. Reprogram the timestamp addender register with the old value and set bit5 for ETH\_PTSCR again

#### 33.4.9.8 PTP Trigger Internal Connection to TIM2

When the system time is faster than the target time, the MAC provides a trigger interrupt. Using interrupts introduces known delays and uncertainty in command execution times.

To avoid this uncertainty, the PTP outputs a trigger signal when the system time is faster than the target time. On the input trigger that is internally connected to TIM2. The analysis is carried out by the input capture characteristics of the timer, the output comparison characteristics and the waveform of the timer. If the timer (PCLK1: TIM2 APB1 clock) and the reference clock of the PTP are synchronized, there is no uncertain time left.

The PTP trigger signal may be software connected to the ITR1 input of TIM2, enabled by register control in bit29 SYSCFG of the AFIO\_MAPR register

#### 33.4.9.9 PTP PPS Output signal

The PTP pulse output is used to check the synchronization of different nodes in the network. In order to test the difference between the local slave device clock and the master reference clock, the PPS (second pulse) output of the master and slave devices can be connected to an oscilloscope to measure the difference between the two clocks. The enabling of the PPS output is controlled by a register in the SYSCFG

### 33.5 DMA Controller

DMA has separate send and receive engines, as well as CSR register space. The sending engine sends data from system memory to the Tx FIFO, and the receiving engine sends data from the Rx FIFO to system memory. The controller utilizes descriptors to efficiently move data from the source to the destination with minimal CPU intervention. DMA is designed for packet-oriented data transmission, such as frames in Ethernet. The controller may be programmed to implement interrupting the CPU when frame transmission and reception is complete and in the event of other normal/error conditions. The DMA communicates with the MCU controller through two data structures

- Control and Status Register (CSR)
- Descriptor List and Data Cache

The DMA sends the received frame data to the reception buffer in the system memory, and can also send the data in the reception buffer. The descriptors of system memory are stored in the form of pointers to the cache. There are two descriptor lists: one for receiving and one for sending. The base address of each list is written in the ETH\_DMATDLAR register and the ETH\_DMARDLAR register. The descriptor list is forward-linked (implicitly or explicitly). The last descriptor may point to the first entry to create a ring structure. The explicit linking of the descriptors is achieved by configuring the second address linked in the receive and send descriptors (RDES1 [24] and TDES1 [24]). The descriptor list is located in the physical memory space of the system. Each descriptor can point to a maximum of two cache areas. This allows two physically addressed caches to be used instead of two consecutive caches in memory. The data buffer area is located in the physical memory space of the system and consists of whole frames or partial frames, but cannot exceed a single frame. The cache contains only data. The status of the cache area is displayed in the descriptor. However, a single descriptor cannot span multiple frames, and when the end of a frame is detected, the DMA jumps to the next frame buffer. The data link may be enabled or disabled. The descriptor structure of ring and chain is as follows:

### 33.5.1 Initialization procedure using DMA transfer

The MAC initialization process is as follows:

1. Configuring parameters of system access to the ETH\_DMABMR register;
2. Configuring the ETH\_DMAIER register to mask necessary interrupts;
3. The software driver creates a list of send and receive descriptors, and then writes the start address of each list into the ETH\_DMARDLAR and ETH\_DMATDLAR registers to provide to the DMA;
4. Configuring the MAC registers 1, 2, 3 to select a desired filtering attribute;
5. Configure the MAC ETH\_MACCR register to enable the receive and send working modes, and set the PS and DM bits according to the automatic negotiation result (read from PHY);
6. Write bit 13 and bit 1 of the ETH\_DMAOMR register to 1, and start transmitting and receiving;
7. The state machine of the sending and receiving engine starts to run. First, it tries to get descriptors from various descriptor lists, and then starts sending and receiving operations. The transmitting and receiving processes are independent of each other and can be started or stopped separately.

### 33.5.2 Host Burst Access

If the FB bit of ETH\_DMABMR is configured, the DMA attempts to perform a fixed-length burst transmission at the AHB host interface. The maximum burst length is determined by the PBL. For the 16 bytes

to be read, the receive and send descriptors are always accessed at the largest possible burst size (subject to PBL restrictions).

Only when there is enough space in the transmitting FIFO for the configured burst or number of bytes, the transmitting DMA will initiate data transmission until the end of the frame (when it is less than the configured burst length). The DMA indicates the start address and the number of transmissions required for the AHB master interface. When the AHB interface is configured with a bit fixed length burst, it is transmitted in an optimal combination of INCR4, INCR8, INCR16 and SINGLE. Otherwise (no fixed length burst), INCR and SINGLE are used to transmit data.

The receive DMA will initiate data transmission only if there is enough data in the receive FIFO for the configured burst, or when the end of a frame is detected in the receive FIFO (when it is less than the configured burst length). The DMA indicates the start address and the number of transmissions required for the AHB master interface. When the AHB interface is configured with a bit fixed length burst, it is transmitted in an optimal combination of INCR4, INCR8, INCR16 and SINGLE. Otherwise (no fixed length burst), INCR and SINGLE are used to transmit data. When the AHB interface is configured for address alignment beats, both DMA engines ensure that the first burst transmission initiated by the AHB is less than or equal to the size of the configured PBL. Therefore, all subsequent beats start at addresses aligned with the configured PBL. DMA can only align the address of the beat to size 16 (for PBL > 16) because the AHB interface does not support more than INCR16.

### 33.5.3 Host data buffer alignment

The send and receive data caches do not have any restrictions on start address alignment. In 32-bit system memory, the start address of the cache can be any one of 4 bytes. However, DMA always initiates transmissions with address alignment, without the bus width of byte channels with dummy data required. This usually occurs during transmission at the beginning or end of an Ethernet frame.

#### ■ Example of read cache area:

If the address of the send cache is 0x0000 0FF2 and there are 15 bytes to transfer, then the DMA reads the full 5 words of data (20 bytes) starting at address 0x0000 0FF0, but when sending data to the Tx FIFO, the extra bytes (the first 2 bytes) are dropped. In the same way, the last 3 bytes will also be discarded. The DMA needs to ensure that it is 32-bit data that is transferred to the Tx FIFO, unless it is data at the end of the frame.

#### ■ Example of write cache area:

If the address of the receive cache is 0x0000 0FF2, and 16 bytes of data need to be received, then the DMA will write 5 full 32-bit data starting from the address 0x0000 0FF0 address. But the first 2 bytes of the first transmission and the last 2 bytes of the third transmission will have dummy data.

### 33.5.4 Buffer area size calculation

DMA does not update the size fields in the send and receive descriptors. The DMA will only update its status field. The driver needs the area to calculate the size. The transmission DMA transmits the exact number of bytes to the MAC core (indicated by the buffer size field in TDES1). If the FS bit in the descriptor TDES1 is set to 1, the DMA considers the first transmission from the buffer as the beginning of the frame. If the LS bit in the descriptor TDES1 is set to 1, the DMA treats this transmission from the buffer as the end of the frame. The receiving DMA will continue to send data until the buffer area

is full or a frame of data is sent out. If the descriptor is not marked as last (LS bit in RDES0), but when FS position 1, the buffer corresponding to the descriptor is full and the valid data in the buffer is equal to the value of the size field minus the offset pointed to by the buffer pointer. When the data buffer pointer is aligned with the data bit width, the offset is 0. If the descriptor is marked as last, the buffer may not be full (as shown by the buffer size in RDES1). To calculate the effective amount of data in this final buffer, the driver must read the frame length (the FL bit in RDES0 [29: 16]) and subtract the sum of the buffer sizes of the previous buffer areas in that frame. Typically the receiving DMA will send the start of the next frame at the time of a new description.

Note: Even when the start address of the receive buffer is misaligned with the system data bit width, the system should allocate a receive buffer area with the same size as the system bus width. For example: If the system allocates a 1024-byte receive buffer area with a starting address of 0x1000, the software can program an offset with the starting address of 0x1002 in the receive descriptor. The receiving DMA will supplement dummy data (0x1000 and 0x1001) at the first 2 positions when writing frame data to the buffer area. The actual frame is written from 0x1002. Therefore, due to the offset of the start address, the real effective space in the buffer is 1022 bytes, even though the buffer size is configured to be 1024 bytes.

### 33.5.5 DMA Arbitration

The arbiter inside the DMA is responsible for arbitrating between transmit and receive channel access to the AHB main interface. Two types of quorum methods are supported: round-round and fixed-priority. When the cyclic mode is selected (the DA bit of the ETH\_DMABMR register is 0), the data bus is proportionally allocated by setting the PM bit of the arbiter when the transmitting and receiving DMA request access at the same time. When the DA bit is 1, the receive DMA always takes precedence over the transmit DMA for data access.

### 33.5.6 DMA error status

For any data transfer initiated by the DMA channel, if the slave device replies with an error response, the DMA stops all operations and updates the error bit and fatal bus error bit in the status register (ETH\_DMASR register). The DMA controller can only resume operation after a soft or hard reset of the peripheral and re-initialize the DMA.

### 33.5.7 Tx DMA Configuration of

#### 33.5.7.1 Non-OSF mode (default mode)

Default configuration for sending DMA engine:

Set the transmission descriptor (TDES0-TDES3), and set the OWN bit in TDES0 after establishing the corresponding data buffer area with Ethernet frame data;

1. When the ST position of the ETH\_DMAOMR register is 1, the DMA enters the running state;
2. When entering the running state, the DMA polls the transmit descriptor list. When the polling is complete, it continues in sequence descriptor ring order or chain order;
3. If the DMA detects a descriptor marked as CPU owned, or an error state occurs, the send buffer (bit 2 of the ETH\_DMASR register) becomes unavailable and the regular interrupt statistics bit is set (bit 16 of the ETH\_DMASR register), and the send engine flow jumps to step 9;

4. If the acquired descriptor is marked as owned by DMA (TDES0 [31]) is set to 1), DMA will decode the transmit data buffer address from the acquired descriptor;
5. The DMA fetches the transmission data from the memory and transmits the data;
6. If an Ethernet frame is stored on a data buffer in multiple descriptors, DMA closes the intermediate descriptor and fetches the next descriptor. Steps 3, 4, and 5 are repeated until the end of the frame is transmitted;
7. When the frame is transmitted, if the IEEE 1588 timestamp function is enabled, the value of the timestamp is written to the transmit descriptors (TDES2 and TDES3) containing the frame end buffer. The status information is written to the transmission descriptor TDES0. Since the OWN bit is cleared in this step, the CPU now starts to occupy the descriptor. If the timestamp is not enabled, the DMA will not modify TDES2 and TDES3;
8. The transmission interrupt (ETH\_DMASRregister [0]) is set after completion of the transmission of the frame in which the "completion interrupt" (TDES1 [31]) is set in its last descriptor. The DMA engine goes back to step 3
9. In the suspended state, when the DMA receives a send poll request, the DMA attempts to refetch the descriptor (then returns to step 3) and the underflow interrupt status bit is cleared.

Tx DMA sending process in default mode:

### 33.5.7.2 OSF mode

When in the running state, the transmitting process may acquire both frames simultaneously without turning off the state descriptor of the first frame (if the OSF bit in ETH\_DMAOMR is set). When the transmission of the first frame is completed, it immediately polls the transmission descriptor list of the second frame. If the second frame is valid, the transmission flow transmits the frame before writing the status information of the first frame. In OSF mode, DMA operates as follows in the running state:

1. The DMA operation is the same as steps 1-6 of TxDMA (default mode);
2. There is no need to close the last descriptor of the previous frame, DMA will directly take the next descriptor;
3. If the acquired descriptor is occupied by the DMA, the DMA decodes the address of the send buffer. If the DMA does not occupy the rights of the descriptor, the DMA will enter a suspended state and jump to step 7;
4. DMA takes frame data from memory and sends it, and the end of the frame is sent directly. If the frame is split into multiple descriptors, the intermediate descriptor is turned off;
5. The DMA waits for the transmission status and clock stamp of the previous frame, and when the status becomes certain, if the timestamp is captured, the DMA writes the timestamp value to TDES2 and TDES3. The DMA then writes the status (cleared OWN bit) to the corresponding TDES0, thereby closing the descriptor. DMA does not modify TDES2 and TDES3 if the timestamp is not enabled in the previous frame;
6. If the send interrupt is enabled and juxtaposed, the DMA fetches the next descriptor and then performs step 3 (if the status is normal). If the status of the previous frame is an underflow error, the DMA enters suspend mode (step 7);
7. In suspended mode, if the suspended state and clock stamp are received by the DMA, the DMA will write the timestamp to TDES2 and TDES3, then write the state to the corresponding TDES0, then set the relevant interrupt and return to the suspended state.
8. Only when a send poll command (ETH\_DMATPDR register) is received, the DMA leaves the suspended state and then enters the running state (proceed to steps 1 and 2).

### 33.5.7.3 The process of sending the frame

The transmitting DMA expects that the data buffer can contain the entire Ethernet frame, except for the preamble, padding field, and FCS field. The destination address, source address, and type/length fields contain some data. If the transmit descriptor shows that the MAC controller must turn off CRC and padding insertion, the buffer must have a full Ethernet frame (excluding the preamble), including the CRC bytes. A frame may be a data link and span multiple buffers. Frames must be separated by a first buffer descriptor (TDES1 [29]) and a last buffer descriptor (TDMES1 [30]). When transmission starts, TDES1 [29] needs to be set in the first descriptor. When it is set to 1, frame data starts to be transmitted from the buffer area to the Tx FIFO. If the last descriptor of the current frame, TDMES0 [29], is cleared, the sending flow attempts to get the next descriptor. The sending process expects TDES1 [29] to be cleared in this descriptor. If TDES1 [30] is cleared, it indicates that an intermediate buffer exists. If TDES1 [30] is set, it indicates the last buffer area of the frame. When the last buffer

area of the frame is sent, the DMA will write the last status information to the word of transmit descriptor 0 (TDES0), which sets the last segment in transmit descriptor 0 (TDES1 [30]). At the same time, if the completed interrupt (TDES1 [31]) is set, the send interrupt flag (bit0) in the ETH\_DMASR register will be set to 1, and the next descriptor will be taken away and repeated. The transmission of the actual frame begins after the transmission FIFO reaches the programmable transmission threshold (ETH\_DMAOMRregister[16:14]), or when a complete frame is saved to the FIFO. And of course the store-and-forward mode. When DMA completes sending a frame, it will release the occupancy (the OWN bit of TDES0 [31] is cleared)

#### 33.5.7.4 Send polling is suspended

The send polling process is suspended by the following conditions:

- The DMA detects that the descriptor is occupied by the CPU, and the unavailability flag of the sending buffer area is set to 1 (bit [2] of the ETH\_DMASR register). If it wants to continue, the driver must grant ownership of the descriptor to the DMA, and then issue a polling request command;
- When a transmission error due to an underflow is detected, the frame transmission is aborted. The appropriate Transport Descriptor 0 (TDES0) bit is set. If the second case is sent, both the total exception interrupt (in the ETH\_DMASR register[15]) and the send underflow bit (in the ETH\_DMASR register[5]) are set to 1, and this information is written to descriptor 0, causing a pause and suspend. If the DMA enters the suspended state because of the first case, both the total normal interrupt bit (ETH\_DMASRregister[16]) and the transmit buffer unavailable bit (ETH\_DMASR register[2]) are set to 1. In both cases, the location of the send list is saved, which is the next descriptor of the last descriptor closed by DMA. The driver must issue a send poll demand command after the correction pause.

#### 33.5.7.5 Send DMA descriptor

At least one descriptor is required for each frame transmission

- TDES0: transmit descriptor word 0

TDES0 contains the status of the transmitted frame and the owner attribute of the descriptor. The status bit is only valid at LS position 1, so when a frame is transmitted through multiple descriptors, the status bit is only valid at the last descriptor.

|         |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |

| 17      | <b>TTSS:</b> Transmit time stamp status<br><b>The status bit indicates that a timestamp was captured in the transmit frame</b><br>When set to '1': TDES2 and TDES3 contain the captured timestamp value. This bit is only valid when the LS bit is 1                                                                                                                                                                                                                                                                                                                                                                             |
| 16      | <b>IHE:</b> When IP header error is set to '1', it indicates that the checksum load shedding function has detected an IP header error. This bit is only valid when the send checksum load shedding function is enabled. Otherwise, when an IP header error is detected, the IPv4 header checksum will still be inserted if the Ethernet type field shows IPv4 payload                                                                                                                                                                                                                                                            |
| 15      | <b>ES:</b> Error Summary<br>TDES0 [16]: IP header error<br>TDES0 [14]: Jabber timer overflow TDES0 [13]: frame clear TDES0 [12]: payload checksum error TDES0 [11]: carrier loss TDES0 [10]: no carrier TDES0 [9]: late collision TDES0 [8]: too much collision TDES0 [7]: too much delay TDES0 [6]: underflow error                                                                                                                                                                                                                                                                                                             |
| 14      | <b>JT:</b> When the Jabber timer overflow (Jabber timeout) is set to '1', it indicates that a verbose timeout has occurred at the MAC sender. This bit is set to '1' only if the JD bit of the MAC set register is not '1'.                                                                                                                                                                                                                                                                                                                                                                                                      |
| 13      | <b>FF:</b> When Frame flushed is set to '1', it means that the DMA/MTL clears the frame from the FIFO due to a command issued by the CPU.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                        |
| 12      | <b>PCE:</b> Payload Checksum Error<br>When set to '1', it means that the checksum load shedding function detects an error and does not insert the checksum into TCP, UDP, and ICMP valid data. There are two kinds of errors: 1. The actual number of valid data bytes is less than the value of the valid data length field of the IP header; 2 In store-and-forward mode, before the checksum has been calculated, the transport layer starts forwarding frame data to the MAC transmitter. The second case occurs only if the depth of the transmission FIFO is less than the length of the Ethernet frame to be transmitted. |
| 11      | <b>When LOC:</b> Loss of carrier is set to '1', it indicates that a carrier loss occurred at the time of frame transmission (at the time of transmission, the MII_CSR signal is invalid in one or more transmission clock cycles). This bit is only valid in half-duplex mode when there is no collision in the transmitted frame.                                                                                                                                                                                                                                                                                               |
| 10      | <b>NC:</b> When No carrier is set to '1', it indicates that the carrier sense signal of the PHY is invalid at the time of frame transmission.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                    |
| 9       | <b>LC:</b> When Late collision is set to '1', it indicates that transmission of the frame is stopped because a collision occurs after a collision window (64 bytes of time including the preamble in MII mode) at the time of transmission. If error position '1' is overflowed, this bit is invalid.                                                                                                                                                                                                                                                                                                                            |
| 8       | <b>EC:</b> When Excessive collision is set to '1', it indicates that transmission of the frame is stopped because 16 consecutive collisions occur during transmission. If the RD (no retry) bit of the MAC set register is '1', then after a collision, the bit is set '1' and the transmission is aborted.                                                                                                                                                                                                                                                                                                                      |
| 7       | <b>VF:</b> When VLAN frame is set to '1', it indicates that the transmitted frame is a VLAN frame                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                |
| 6: 3    | <b>CC:</b> Collision count<br>This 4-bit value records the number of collisions that occur before the frame is sent out. When the EC bit (TDES0 [8]) is '1', the bit is invalid                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| 2       | <b>ED:</b> When Excessive deferral is set to '1', it means that when the delay check bit of the MAC setting register is '1', the transmission is terminated due to the delay of more than 24288 bits                                                                                                                                                                                                                                                                                                                                                                                                                             |
| 1       | <b>UF:</b> When data Underflow error (Underflow error) is set to '1', it means that data from RAM to MAC is too late, causing the MAC to stop sending the frame. A data underflow error indicates that the DMA encountered an empty buffer when sending the frame. The transmission process enters the suspended state, and the transmission data underflow bit (ETH_DMASR register bit 5) and the transmission status bit (ETH_DMASR register bit 0) are set to '1'                                                                                                                                                             |

|   |                                                                                                                                                                            |
|---|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 0 | <b>DB:</b> When the Deferred bit is set to '1', it indicates that the MAC delays transmission because the carrier is occupied. This bit is only valid in half-duplex mode. |
|---|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

■ TDES1: transmit descriptor word 1

TDES1 contains the size of the buffer and the control bits of other control descriptor chains or rings when transmitting frames

|        |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                      |

### 33.5.8 Rx DMA Configuration of

The receiving step of the receiving DMA engine is as follows:

1. The CPU sets the receive descriptors (RDES0-RDES3) and sets the OWN bit;
2. Once the SR position of the ETH\_DMAOMR register is 1, the DMA enters the run mode. In running mode, the DMA polls the list of receive descriptors in an attempt to get the idle descriptor. If the fetched descriptor is not idle (CPU occupied), the DMA will enter a suspended state and jump to step 9;
3. Decoding the address of the received data buffer area by the acquired descriptor DMA;
4. The received frame is processed and placed in the data buffer area of the descriptor;
5. When the buffer area is full or a frame of data is transmitted, the receiving engine will exchange the next descriptor;
6. If the current frame has been transmitted, the DMA proceeds to step 7. If the DMA does not occupy the next acquired descriptor and the frame transmission has not been completed, the DMA will set the descriptor error position 1 in RDES0 (unless emptying is prohibited). DMA will close the current descriptor (by clearing the OWN bit) and mark it as an intermediate descriptor by clearing the LS bit in the RDES1 value (if clearing is not disabled, mark it as the last descriptor), and then perform step 8. If DMA occupies the next descriptor but the current frame has not been sent, DMA will close the current descriptor as an intermediate descriptor and return to step 4;
7. If the IEEE 1588 timestamp is enabled, the DMA writes timestamp data to RDES2 and RDES3 of the current descriptor. The status information of the received frame is then written into the status word (RDES0), the OWN bit is cleared, LS position 1.
8. The receiving engine checks the OWN bit of the latest descriptor. If the CPU owns the descriptor (OWN bit is 0), the receive buffer area unavailable bit is set (in the ETH\_DMASR register[7]) and the DMA receive engine enters a suspended state (step 9). If the DMA has a descriptor, it returns to Step 4 to wait for the next frame
9. When the receiving engine enters the suspended state, it will clear some frames in the receiving FIFO (the clear control bit can be set);
10. When a reception poll request is given or the start of the next frame is available from the reception FIFO, the reception DMA exits the suspended state. The engine goes back to step 2 and refetches the next descriptor

The DMA does not acknowledge the receive status until it completes the timestamp write-back and is ready to perform the status write-back to the descriptor. If the timestamp function is enabled by the software, the DMA writes all 1s to RDES2 and RDES3 when a valid timestamp value is invalid for the frame (e.g., the receive FIFO is full when the timestamp is written). Otherwise (timestamp is not enabled), RDES2 and RDES3 do not change.

### 33.5.8.1 Get Receive Descriptor

The receiving engine will always attempt to make additional descriptor acquisitions for incoming frames. Attempts to get a descriptor when any of the following conditions are met:

- When the DMA is running, immediately set the receive start/receive bit (ETH\_DMAOMR bit [1])
- The data buffer area of the current descriptor is full before the end of the received frame
- The frame has finished receiving, but the currently received descriptor is not closed
- The reception process is suspended because the CPU occupies the buffer area or a new frame is received
- Issue a receive poll request

### 33.5.8.2 Receive frame process

The MAC transmits and receives frames only if the frame has passed address filtering and the size of the frame is greater than or equal to the FIFO threshold configured by F, or uses store-and-forward mode. If frame address filtering fails, it will be discarded directly (unless ETH\_MACFFR [31] is set to receive all frames). Frames shorter than 64 bytes (configurable) are cleared from the receive FIFO due to collision or early termination. The DMA block begins transmitting frame data to the receive buffer area pointed to by the current descriptor. The DMA sets the first descriptor (RDES0 [9]) after the AHB interface can receive data transmission. The descriptor is released when the OWN (RDES0 [31]) bit is reset to 0, either when the data buffer is filled or when the last segment of the frame is

transmitted to the receive buffer. If a frame is included in a descriptor, the first descriptor (RDES0 [9]) and the last descriptor (RDES0 [8]) identification bits are both set to 1. After the DMA sets 1 the last descriptor in the previous descriptor and releases the RDES0 status bit, it starts fetching the next descriptor. The DMA then sets the receive interrupt bit (bit [6] of the ETH\_DMASR register) to 1. The same process is repeated unless the DMA encounters a descriptor marked as being owned by the CPU. If this is sent, the receiving process will set the receive buffer invalid bit (ETH\_DMASR bit [7]) to 1 and enter the suspended state. The position in the receive list will be preserved.

### 33.5.8.3 Receiving process suspended

If a new receive frame arrives while the receive process is suspended, the DMA refetches the descriptor currently in memory. If the descriptor is owned by the DMA, the receiving process will re-enter the running state to start the reception of the frame. If the descriptor is still owned by the CPU, the DMA discards the current frame at the top of the Rx FIFO by default and increments the lost frame counter. This process repeats if there is more than 1 completion frame in the Rx FIFO. Dropping or refreshing frames on top of the Rx FIFO can be avoided by setting the DMA mode of operation register bit 24 (DFRF). In this case, the receiving process sets the receiving buffer area unavailable status bit and returns to the suspended state.

### 33.5.8.4 DMA receive descriptor

#### ■ RDES0: Receive Descriptor Word 0

RDES0 includes information such as the state of the received frame, the length of the frame, and the assignment of the descriptor. These status bits are only valid when the LS position is 1.

|        |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |

#### ■ RDES1: Receive Descriptor Word 1

RDES1 contains the cache size and other control bits that control the ring or chain descriptor

|        |                                                                                                                                                                                                                                                                                                                                                                                                         |
|--------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 31     | <b>DIC:</b> When the reception completion interrupt (Disable interrupt on completion) is turned off and set to '1', the RS bit (bit 6) of the ETH_DMASR register is not set for the frame indicated by the current descriptor when frame reception is completed. This also prevents RS bit triggered interrupts from occur<br>This bit is valid only if the last descriptor bit (RDES0 [8]) is set to 1 |
| 30: 26 | Reserved                                                                                                                                                                                                                                                                                                                                                                                                |
| 25     | <b>RER:</b> When the Receive end of ring is set to '1', this bit indicates that the current descriptor is the last in the descriptor queue. The DMA will return to that base address of the descriptor queue to take the next descriptor, so that the descriptor queue forms a ring structure                                                                                                           |
| 24     | <b>RCH:</b> When the Second address chained list (Second address chained) is set to '1', this bit indicates that the second address in the descriptor is the address of the next descriptor, not the second cached address. When this bit is '1', the value of RBS2 (TDES1 [28: 16]) can be ignored. The role of RDES0 [15] takes precedence over the native (RDES0 [14]).                              |
| 23: 22 | Reserved                                                                                                                                                                                                                                                                                                                                                                                                |
| 21: 11 | <b>RBS2:</b> The size of Transmit Buffer 2 (Transmit Buffer 2 Size) represents the size of the second buffer area, and the buffer size must be a multiple of 4. This bit is invalid when RCH is 1                                                                                                                                                                                                       |
| 10: 0  | <b>RBS1:</b> The size of Transmit Buffer 1 (Transmit Buffer 1 Size) represents the size of the first buffer area, and the buffer size must be a multiple of 4. If the value is 0, DMA ignores the buffer and uses buffer 2 or the next descriptor (depending on the RCH)                                                                                                                                |

#### ■ RDES2: Receive Descriptor Word 2

RDES2 contains the address of the first buffer of the descriptor

|        |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
|--------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 31 : 0 | Buffer 1 Address Pointer (Buffer 1 Address Pointer)<br>This bit segment represents the physical address of buffer 1, and there is no restriction on the alignment of buffer address. When the RDES2 value is used to store the beginning of a frame, the DMA uses the configured value to generate its address. During the transmission at the beginning of the frame, the DMA performs a write operation with the RDES2 [1: 0] bit as 0, but the frame data is shifted according to the actual buffer address pointer. |
|--------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

#### ■ RDES3: transmit descriptor word 3

RDES3 contains the second buffer of the descriptor or the address of the next descriptor

|        |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                   |
|--------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 31 : 0 | Buffer 2 Address Pointer/Next Descriptor Address (Buffer 2 Address Pointer/Next Descriptor Address)<br>When the ring descriptor architecture is used, this bit segment represents the physical address of Buffer 2<br>When RCH in descriptor word 1 is set to 1, this bit segment represents the next descriptor physical address, and the cache address must be aligned with the bus width.<br>When RCH is set to 0, there is no limit to the value of RDES3, except when the RDES3 value is used to store the beginning of the frame, the DMA uses the configured value to generate its address |
|--------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

### 33.5.9 Descriptor format to enable IEEE1588-2005 timestamps

If the software enables the IEEE1588-2005 feature, the contents of the DES2 and DES3 descriptor regions have different meanings when the DMA turns off the descriptor (clears the OWN bit of DES0). The timestamps are updated to DES2 and DES3 before DMA clears the OWN bit of DES0.

#### 33.5.9.1 Send descriptor

The send descriptor has more control (TTSE and TTSS) to send the timestamp. As shown in the figure below, when the software sets TTSE (when OWN is 1), it means that the timestamp will be generated for sending Ethernet frames. DMA will update the timestamps to TDES2 and TDES3 before the descriptor is turned off.

■ TDES0:

|    |                                                                                                                                                                                                                                                                                                                                                                            |
|----|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 17 | <p>TTSS: Transmit Timestamp Status</p> <p>This field is a status bit indicating that a timestamp has been captured for the corresponding transport frame. When this bit is set, both TDES2 and TDES3 have timestamp values captured for the transmission frame.</p> <p>This field is valid only if the last segment control bit (TDES1 [30] in the descriptor) is set.</p> |
|----|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

■ TDES1:

|    |                                                                                                                                                                                                                                                                        |
|----|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 22 | <p>TTSE: Transmit Timestamp Enable</p> <p>When set, this field enables the IEEE1588 hardware timestamp for the transmit frame described by the descriptor.</p> <p>This field is only valid if the first segment control bit (TDES1 [29] in the descriptor) is set.</p> |
|----|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|

The transport descriptor format and field description remain unchanged when created by software (OWM is 1), however, when the last descriptor is turned off by DMA and the IEEE1588 function is enabled, the TDES2 and TDES3 contents are timestamped updated.

■ TDES2:

|       |                                                                                                                                                                                                                                                                               |
|-------|-------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 31: 0 | <p>TTSL: Transmit Frame Timestamp Low</p> <p>The DMA updates this field with the least significant 32 bits of the timestamp captured for the corresponding transport frame. This field has a timestamp only if the last segment control bit (LS) in the descriptor is set</p> |

### 33.5.9.2 Receive descriptor

When the timestamp is enabled, the receive descriptor format is as follows:

When the receive descriptor is off and the timestamp is enabled, RDES2 and RDES3 of the receive descriptor have fields of different meanings.

■ RDES2:

|       |                                                                                                                                                                                                                                                                                                                                                                                                            |

### 33.5.9.3 DMA interrupts

There are a variety of events that can generate an interrupt. The ETH\_DMASR contains all bits that can cause an interrupt, while the ETH\_DMAIER register contains every interrupt enable bit that can generate an interrupt event.

There are two groups of interrupts, as described in the ETH\_DMASR register, which can be divided into normal group and abnormal group. The interrupt can be cleared by writing '1' to the corresponding bit. If all enabled interrupts in a group are cleared, the summary bits of that group are also cleared accordingly. If the interrupt is triggered by the MAC controller, the TSTS bit or the PMTS bit of the ETH\_DMASR is set high.

Interrupt events are not queued, that is, if an interrupt occurs, another interrupt will not occur before responding to it. For example, the receive interrupt bit (ETH\_DMASR [6]) indicates that one or more frames have been received in the buffer, and the interrupt handler needs to retrieve all DMA-occupied descriptors from beginning to end.

Multiple events that can cause interrupts at the same time can generate only one interrupt. The interrupt handler needs to check the ETH\_DMASR register to determine the source of the interrupt. After the corresponding bit of the ETH\_DMASR register is properly cleared, no interrupt will be generated unless another interrupt event occurs. For example, the controller generates a receive interrupt (ETH\_DMASR [6] is '1'), and after the interrupt handler reads out the ETH\_DMASR register, the receive

buffer unavailable(ETH\_DMASR [7] is '1') event occurs; After the receive interrupt is cleared first, a new interrupt is generated because the receive cache unavailable interrupt is still valid and needs to be processed

### 33.6 Ethernet interrupt

The Ethernet controller has two kinds of interrupt vectors: one for regular operation-induced interrupts and one for Ethernet wake-up time (mapped at EXTI line 31)

The first is an interrupt generated for MAC and DMA, as described in the sections of MAC interrupts and DMA interrupts. The second is generated by the PMT for wake-up events. The wake-up event is an interrupt generated to exit the low power mode. When a wake-up event mapped to EXTI 31 occurs, if enable is turned on, it is detected that its rise is used to exit the low power mode.

When the Ethernet wake-up event is mapped to the EXTI line 31, once the wake-up event occurs, if the PMT interrupt of the MAC is enabled, and the interrupt is generated when the rising edge is detected by the EXTI line 31 is enabled, then two interrupts will occur simultaneously.

There is a watchdog timer outside the Ethernet network (see ETH\_DMARSWTR register), which can be used to flexibly control the setting of the RS bit (ETH\_DMASR [6]). If a value other than zero is written to the watchdog and no receive interrupt is enabled in the descriptor of the received frame (RDES1 [31] = 0), the watchdog timer is activated when the receiving DMA receives the frame into system memory without setting the RS bit to '1'. The RS bit is set to '1' only when the watchdog timer is decremented to 0, and an interrupt occurs if the corresponding RIE interrupt is enabled. Before the watchdog timer is decremented to 0, if a frame is received, the frame descriptor enables the receive interrupt, and the RS bit is set to '1' while the watchdog timer is turned off.

Note: Reading the PMT control and status registers automatically clears the wake-up frame reception and Magic Packet reception interrupt flag bits. However, since the register in which these flags are located is located in the CLK\_RX domain, there may be a considerable delay before the application

sees these flags cleared. This delay will be particularly long if the RX clock is slow (such as in 10M-bit mode) and the AHB bus clock frequency is high.

Since the interrupt request generated by PMT to the CPU is also in the same register in the RX\_CLK field, the CPU may incorrectly call the interrupt program again after reading the PMT\_CSR register. Therefore, the application needs to query the wake-up frame reception and Magic Packet reception flag bits in the interrupt until they become 0 before exiting the interrupt service routine.

## 33.7 TIMx registers

### 33.7.1 Ethernet MAC configuration register (ETH\_MACCR)

Address offset: 0x0000

Reset value: 0x0000 0000

| 4    | DC       | RW | 0 | Delay checking (Deferral check)<br>1: Enable the delay detection function when the sending state machine delays the sending by more than 24288 bits. The MAC issues a frame abort state and pulls up the excessive delay error flag bit in the transmitted frame. Delay counting will be turned on when the data is ready to be sent, and counting will be interrupted if the CRS signal is pulled up. The delay time does not accumulate. If the sender is delayed by 10000 bits, then sends, collides, bounces, and then must be delayed again after the fallback is complete, the delay is cleared and counted again<br>Works in half-duplex mode only<br>0: The delay check function is turned off, and the MAC delays until the CRS signal becomes invalid.<br>Note: For Half Duplex Mode Only |

| 0 | MB  | RW | 0 | MII busy<br>This bit must be read to 0 before writing to the eth_macmiar and eth_macmiidr registers,<br>During writing to ETH_MACMIAR, this bit must also be reset to 0. During a PHY register access, this bit can be set to 1 to show that a read and write operation is in progress. In a write operation, the data in ETH_MACMIIDR must remain valid until the bit is cleared by the MAC. In the process of reading, the data in ETH_MACMIIDR is not valid until the bit is cleared by the MAC. ETH_MACMIAR cannot be written until this bit is cleared. |

| 15: 0  | VLANTI   | RW  | 0           | VLAN tag identifier<br>It contains an 802.1 Q VLAN tag to identify the VLAN frame and compares it to the 15th and 16th bytes of the received VLAN frame. bit [15:13] is the user priority, bit [12] is the canonical format indicator (CFI), and bit [11: 0] is the VLAN identifier field of the VLAN tag. When the VLANTC bit is set, only the VID (bit [11: 0]) is used for comparison |

### 33.7.9 EthernetMACRemote Wake Frame Filter Register (ETH\_MACRWUFR)

Address offset: 0x0028

Reset value: 0x0000 0000

This register is essentially a pointer to 8 opaque wake-up frame filter registers (using the same offset address). 8 consecutive write operations to this register address (offset 0x0028) can write all 8 wake-up frame filter registers; Eight consecutive reads of this register address (offset 0x0028) can read all eight wake-up frame filter registers

| 4: 3  | RTC      | RW | 0 | Receive threshold control (Receive threshold control)<br>This bit segment controls the threshold point at which the FIFO is received. When the size of the buffer frame in the Rx FIFO is greater than the threshold, the transmission of the frame to the memory is started. In addition, if it is a complete frame, transmission will be turned on even if the size is less than the threshold value. This bit segment is valid when the RSF is cleared<br>00: 64<br>01: 32<br>10: 96<br>11: 128                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                         |
| 2     | OSF      | RW | 0 | Second frame continuous mode (Operate on second frame)<br>1: DMA transmits second frame before receiving status information of first frame                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |
| 1     | SR       | RW | 0 | Start/stop receive<br>1: The receiver enters the running state, and the DMA checks the frame to be transmitted in the transmission list at the current position. The descriptor acquisition attempt is made at the position of the current list (the base address ETH_DMATDLAR register setting of the received list) or from the position held when the transmission was previously stopped. If no descriptor is owned by the DMA, the reception goes into a suspended state and the reception buffer invalid bit is set to 1 (ETH_DMASR [7]). The start receive command is only valid when the receive stops. If the command is issued before the DMA ETH_DMATDLAR register is set, the behavior of DNA is unpredictable.<br>0: The transmission process enters the stopped state after the reception of the current frame is completed. The next descriptor position in the reception list is saved and becomes the current position when reception is restarted. The stop receive command is only valid if the receiving process enters the suspended or running state |

## 34. CAN bus controller

### 34.1 Introduction

The controller local area network (CAN) subsystem consists of two CAN modules and a shared message RAM memory. Please refer to section [Memory Mapping] for the base addresses of these three components.

The CAN module complies with ISO 11898-1: 2015 (CAN Protocol Specification Version 2.0 Parts A, B) and CAN FD Protocol Specification Version 1.0 (CAN with Flexible Data-Rate Specification Version 1.0).

FDCAN1 follows the CAN bus CAN2.0 (2.0 A, CAN2.0B) protocol.

FDCAN2 follows the CAN bus CAN2.0 (2.0 A, CAN2.0B) and CAN FD protocols.

The 1.6 KB message RAM memory can implement the functions of filter (Rx Filter), receive FIFO (Rx FIFO), receive buffer (Rx Buffer), send event FIFO (Tx Event FIFO) and send buffer (Tx Buffer). The message RAM is shared between the FDCAN1 and FDCAN2 modules.

#### 34.1.1 Main features

- ISO 11898-1: 2015 standard is applicable
- CAN FD supports sending and receiving up to 64 data bytes
- Support CAN error logging
- Supports AUTOSAR and SAE J1939
- Support receive filtering function
- Two configurable receive FIFOs
- Individual signal indication when high priority messages are received
- Up to 3 dedicated receiving buffers
- Up to 3 dedicated send buffers
- Configurable send FIFO or queue
- Configurable Send Event FIFO
- Host CPU has direct access to message RAM
- The FDCAN1 and FDCAN2 modules share the same message RAM
- Supports programmable loopback test mode
- Supports maskable module interrupts
- Two clock domains: CAN core clock and APB bus interface clock

### 34.1.2 CAN block diagram

Figure 34-1 Module block diagram

#### CAN kernel

The CAN core contains a protocol controller, receive and send shift registers. It handles all protocol functions of ISO 11898-1: 2015 and supports 11-bit standard ID and 29-bit extended ID.

#### synchronization

The synchronization module synchronizes signals from the APB clock domain to the CAN core clock domain and synchronizes signals from the CAN core clock domain to the APB clock domain.

#### Clocks

The clock of the APB clock domain is the FDCAN control logic clock, and the clock of the CAN kernel clock domain is the FDCAN communication clock, please refer to the section [RCC]. In order to ensure the stability of FDCAN communication, the control logic clock frequency must be greater than or equal to the communication clock frequency.

#### Transmission processing unit

The processing unit controls the transfer of messages from the external message RAM to the CAN core. Up to 32 send buffers can be configured for sending. The transmit buffer may be used as a dedicated transmit buffer, a transmit FIFO (or queue), or a combination of both. The transmission event FIFO stores the transmission timestamp with the corresponding message ID. Cancellation of sending is also supported.

### Receiving processing unit

The processing unit controls the transmission of received messages from the CAN core to the external message RAM. The receive processing unit supports two receive FIFOs (each FIFO is configurable in size) and up to 64 dedicated receive buffers for storing all messages filtered by receive. Unlike the receive FIFO, the dedicated receive buffer is only used to store messages with a specific ID. The reception timestamp is stored with its message. For an 11-bit standard ID, up to 128 filters can be defined; For a 29-bit extended ID, a maximum of 64 filters can be defined.

### APB interface

Connect FDCAN to the APB bus.

### Message RAM

The interface connects the FDCAN access to the external 2KB message RAM via the RAM controller and arbiter.

### Double interrupt line

FDCAN provides two interrupt lines, FDCAN\_INT0 and FDCAN\_INT1. Program the FDCAN\_ILE.EINT0 and FDCAN\_ILE.EINT1 bits to enable or disable the interrupt lines, respectively.

## 34.2 FDCAN functional description

### 34.2.1 Operating mode

#### 34.2.1.1 Software Initialization

Software initialization begins by setting FDCAN\_CCCR.INIT. Software reset, hardware reset, or entering Bus\_Off sets FDCAN\_CCCR.INIT. When FDCAN\_CCCR.INIT is set, both incoming and outgoing messages on the CAN bus stop, and the status of the FDCAN\_TX pin becomes recessive (high). The counter for the Error Logic Management Unit (EML) remains the same. Setting FDCAN\_CCCR.INIT does not change any configuration registers. Clearing FDCAN\_CCCR.INIT completes software initialization, and then the Bitstream Processing Unit (BSP) waits for a sequence of 11 consecutive recessive bits (Bus\_Idle) to appear on the bus to synchronize itself with data transmission on the CAN bus before participating in bus activities and starting message transmission.

The FDCAN configuration register can only be accessed when both FDCAN\_CCCR.INIT and FDCAN\_CCCR.CCE are set. FDCAN configuration registers are shown in the following table.

Table 34-1 FDCAN Configuration Register List

| Register    | Description                                                       |
|-------------|-------------------------------------------------------------------|
| FDCAN_DBTP  | FDCAN Data Bit Time and Prescalation Register                     |
| FDCAN_TEST  | FDCAN test register                                               |
| FDCAN_RWD   | FDCAN RAM Watchdog Register                                       |
| FDCAN_CCCR  | FDCAN CC Control Register                                         |
| FDCAN_NBTP  | FDCAN Nominal Bit Time and Prescalation Register                  |
| FDCAN_TSCC  | FDCAN timestamp counter configuration register                    |
| FDCAN_TOCC  | FDCAN timeout counter configuration register                      |
| FDCAN_TDCCR | FDCAN transmitter delay compensation register                     |
| FDCAN_GFC   | FDCAN global filter configuration register                        |
| FDCAN_SIDFC | FDCAN standard ID filter configuration register                   |
| FDCAN_XIDFC | FDCAN Extended ID Filter Configuration Register                   |
| FDCAN_XIDAM | FDCAN Extension ID and Mask Register                              |
| FDCAN_RXF0C | FDCAN receives FIFO0 configuration register                       |
| FDCAN_RXBC  | FDCAN receive buffer configuration register                       |
| FDCAN_RXF1C | FDCAN receive FIFO1 configuration register                        |
| FDCAN_RXESC | FDCAN receive buffer and FIFO element size configuration register |
| FDCAN_TXBC  | FDCAN send buffer configuration register                          |

|             |                                                       |
|-------------|-------------------------------------------------------|
| FDCAN_TXESC | FDCAN send buffer element size configuration register |
| FDCAN_TXEFC | FDCAN send event FIFO configuration register          |

FDCAN\_CCCR.CCE can only be set or cleared when FDCAN\_CCCR.INIT is set, and automatically cleared when FDCAN\_CCCR.INIT is cleared.

When FDCAN\_CCCR.CCE is set, the following registers are reset:

- FDCAN\_HPMS-High priority message status
- FDCAN\_RXF0S-Receive FIFO 0 status
- FDCAN\_RXF1S-Receive FIFO 1 status
- FDCAN\_TXFQS-Send FIFO/queue status
- FDCAN\_TXBRP-Send buffer request suspended
- FDCAN\_TXBTO-Send buffer Send occurs
- FDCAN\_TXBCF-Send buffer cancellation complete
- FDCAN\_TXEFS-Send event FIFO status
- FDCAN\_TXBAR-Send buffer addition request
- FDCAN\_TXBCR-Send buffer cancellation request

When CCCR.CCE is set, the timeout counter value TOCV.TOC is preset to the value configured by TOCC.TOP.

The following registers are writable only if CCCR.CCE = '0'

- TXBAR-Tx Buffer add request
- TXBCR-Tx Buffer cancellation request

The host can set FDCAN\_CCCR.TEST and FDCAN\_CCCR.MON only if both FDCAN\_CCCR.INIT and FDCAN\_CCCR.CCE are set, and the host can reset FDCAN\_CCCR.TEST and FDCAN\_CCCR.MON at any time. FDCAN\_CCCR.DAR can be set or cleared only if both FDCAN\_CCCR.INIT and FDCAN\_CCCR.CCE are set.

### 34.2.1.2 Normal operations

After FDCAN is initialized and FDCAN\_CCCR.INIT is cleared, FDCAN synchronizes itself with the CAN bus and is ready to communicate. When receiving a message, the message received through the receive filter (containing the message ID and DLC) is stored in a dedicated receive buffer, either receive FIFO or receive FIF1. When sending messages, initialize or update the dedicated send buffer and/or send FIFO (queue) first. Automatic sending after receiving a remote frame is not supported.

### 34.2.1.3 CAN FD operation

There are two types of CANFD frame transmission, the first is CANFD frame without bit rate switching, and the second is CANFD frame with bit rate switching (the transmission bit rate of the control segment, data segment and CRC segment is higher than that at the beginning and end of the frame).

The r0 bit in the classic CAN (ClassicalCAN) standard frame (after the IDE bit, the reserved bit in the standard frame format) and the r1 bit in the extended frame (after the RTR bit, the first reserved bit in the extended frame format) are decoded as the FDF bit in the CANFD frame format. The FDF bit is implicit (logic 1) to indicate a CANFD frame, and explicit (logic 0) to indicate a classic CAN frame. In the CANFD frame, two bits of res and BRS (BitRateSwitch) after the FDF bit determine whether to switch the bit rate in the CANFD frame, and indicate that the bit rate has been switched by res explicit and BRS implicit. The res bit implicit encoding is reserved for future protocol extensions. If both the

FDF bit and the res bit in the frame received by FDCAN are implicit, a protocol exception event will be issued by setting FDCAN\_PSR.PXE. If protocol exception handling is enabled (FDCAN\_CCCR.PXHD = 0), FDCAN will change the working state from receive (FDCAN\_PSR.ACT = 0b10) to synchronous (FDCAN\_PSR.ACT = 0b00) at the next sampling point. If protocol exception handling is disabled (FDCAN\_CCCR.PXHD = 1), FDCAN treats the implicit res bit as a format error and will respond with an error frame.

The CAN FD mode is enabled by programming FDCAN\_CCCR.FDOE. If FDCAN\_CCCR.FDOE = 1, transmission and reception of CAN FD frames are enabled. Classic CAN frames are always available for transmission and reception. Whether to transmit a CAN FD frame or a classic CAN frame CAN be configured by the FDF bit in the corresponding transmit buffer element. If FDCAN\_CCCR.FDOE = 0, the received frame is treated as a classic CAN frame, and an error frame is transmitted when the CAN FD frame is received. If the CAN FD mode is disabled, no CAN FD frame is transmitted even if the FDF position 1 of the buffer element is transmitted. You can change FDCAN\_CCCR.FDOE and FDCAN\_CCCR.BRSE only if FDCAN\_CCCR.INIT and FDCAN\_CCCR.CCE are both set.

If FDCAN\_CCCR.FDOE = 0, the setting of the FDF and BRS bits is ignored, and the frame is transmitted in the classic CAN format.

If FDCAN\_CCCR.FDOE = 1 and FDCAN\_CCCR.BRSE = 0, only the FDF bits of the transmit buffer element are evaluated.

If FDCAN\_CCCR.FDOE = 1 and FDCAN\_CCCR.BRSE = 1, the bit rate switching transmission of the CAN FD frame is enabled. The transmit buffer elements of all FDF and BRS position bits are transmitted in a bit rate switched CAN FD format.

It is recommended to switch modes during CAN operation only if the following conditions are met:

- The failure rate of the CAN FD data phase is significantly higher than that of the CAN FD arbitration phase. In this case, the transmitted CAN FD bit rate switching should be disabled.
- During system startup, all nodes will send classic CAN messages before being verified to be able to communicate in CAN FD format. If verified, all nodes switch to CAN FD operation.
- Wake-up messages in CAN Partial Networking must be sent in classic CAN format.

When EOL programming (End-of-line programming), not all nodes support CANFD, and non-CANFD nodes remain in silent mode until the end of programming. Subsequently, all nodes switch back to classic CAN communication.

In the CANFD format, the encoding (corresponding data byte length) of DLC codes 0 to 8 is the same as that of classic CAN, and the encoding of codes 9 to 15 is different from that of classic CAN, as shown in the following table

Table 34-2 DLC encoding in FDCAN

| DLC encoding    |             | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9  | 10 | 11 | 12 | 13 | 14 | 15 |
|-----------------|-------------|---|---|---|---|---|---|---|---|---|----|----|----|----|----|----|----|
| Data Byte count | Classic CAN | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 8  | 8  | 8  | 8  | 8  | 8  | 8  |
|                 | CAN FD      | 0 | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 12 | 16 | 20 | 24 | 32 | 48 | 64 |

In a CAN FD frame, if the BRS bit is implicit, the bit duration will be switched within the frame after the BRS (bit rate switching) bit. Before the BRS bit, in the CAN FD arbitration section, the bit duration is executed as defined by the register FDCAN\_NBTP (Nominal Bit Timing & Prescaler Register). In the

following CAN FD data segment, the bit duration is executed according to the definition of the register FDCAN\_DBTP (Data Bit Timing & Prescaler Register). The bit duration is switched back from the data segment bit duration after the CRC delimiter, or when an error is detected, whichever occurs first.

The maximum configurable bit rate of the CAN FD data segment depends on the CAN communication clock frequency. For example, if the CAN communication clock frequency is 20 MHz and the shortest configurable bit time is 4 time slices (tq), the bit rate of the data phase is 5 Mbps.

In CAN FD data frame formats with and without bit rate switching, the value of bit ESI (Error Status Indicator) is determined by the error state of the transmitting node at the beginning of transmission. If the transmitting node is in an error passive state, the ESI is transmitted as a recessive bit, otherwise it is transmitted as a dominant bit.

#### 34.2.1.4 Transceiver delay compensation

In the data segment transmitted by CAN FD, only one node sends, and all other nodes are receiving nodes. The length of the bus has no effect. When transmitting over pin FDCAN\_TX, FDCAN receives the transmitted data from its local CAN transceiver over pin FDCAN\_RX. Received data is delayed due to transmitter delay, and if this delay is greater than TSEG1 (the time period before the sampling point), an in-bit error is detected. In order to make the data segment time shorter than the transmitter delay, delay compensation is introduced. Without transmitter delay compensation, the bit rate of the CAN FD frame data segment will be limited by the transmitter delay.

The protocol unit of FDCAN implements a delay compensation mechanism to compensate for the transmitter delay, thereby enabling transmission at a higher bit rate in the CAN FD data segment without being affected by the specific CAN transceiver delay.

In order to check whether the data segment of the transmitting node has bit errors, the delayed transmitted data is compared with the received data at the second sampling point SSP. If a bit error is detected, the transmitting node will react to the bit error at the next regular sampling point. In the quorum segment, delay compensation is always disabled.

Transmitter delay compensation supports configurations where the data bit time is shorter than the transmitter delay, as described in detail in ISO 11898-1: 2015, and is enabled by setting FDCAN\_DBTP.TDC.

The received bits are compared with the transmitted bits at the second sampling point SSP. The position of the SSP is defined as the sum of the delay measured from the FDCAN transmit output pin FDCAN\_TX through the transceiver to the receive input pin FDCAN\_RX and the transmitter delay compensation offset configured by FDCAN\_TDCR.TDCO. The transmitter delay compensation offset is used to adjust the position of the SSP in the received bits (e.g. half the bit time of the data segment). The position of the second sampling point is rounded down to the next integer mtq (Minimum time quantum, that is, the minimum time slice, which is one FDCAN communication clock cycle).

FDCAN\_PSR.TDCV displays the actual transmitter delay compensation value. When FDCAN\_CCCR.INIT is set, FDCAN\_PSR.TDCV is cleared; When FDCAN\_DBTP.TDC is set, FDCAN\_PSR.TDCV is updated each time an FD frame is transmitted.

For transmitter delay compensation implemented in FDCAN, the following boundary conditions must be considered:

- The sum of the measured delay from FDCAN\_TX to FDCAN\_RX and the configured transmitter delay compensation offset FDCAN\_TDCR.TDCO must be less than 6 bits of the data segment.
- The sum of the measured delay from FDCAN\_TX to FDCAN\_RX and the configured transmitter delay compensation offset FDCAN\_TDCR.TDCO must be less than or equal to 127mtq. If this sum is greater than 127 mtq, the transmitter delay compensation uses a maximum value of 127 mtq.
- The data segment ends at the sampling point of the CRC delimiter and will stop checking the received bit at the SSP.

If transmitter delay compensation is enabled by programming FDCAN\_DBTP.TDC = 1, the measurement starts at the falling edge of the FDF bit to res bit of each CAN FD frame. When the edge is detected on the FDCAN\_RX pin of the transmitting node, the measurement is stopped. The resolution of this measurement is one mtq.

Figure 34-2 Transceiver Delay Measurement

In order to avoid dominant glitches in the received FDF bits, the delay compensation measurement is ended before the falling edge of the received res bit, resulting in an advance of the SSP position, the transmitter delay compensation filtering window may be enabled by programming FDCAN\_TDCR.TDCF, thereby defining a minimum value of the SSP position. The dominant edge on the FDCAN\_RX pin causes the SSP position to be more advanced, but this will be ignored for transmitter delay measurements. When the SSP position is at least FDCAN\_TDCR.TDCF and the FDCAN\_RX pin is low, the measurement stops.

#### 34.2.1.5 Limited operating mode

In restricted operating mode, nodes can receive data frames and remote frames, and can acknowledge valid frames, but do not send data frames, remote frames, active error frames, or overload frames. In the event of an error or overload condition, the dominant bit is not sent, but waits for a bus idle condition to occur to resynchronize to CAN communication. The error counters (FDCAN\_TDCR.REC, FDCAN\_TDCR.TEC) are frozen during the error logging (FDCAN\_TDCR.CEL) action. The host can set FDCAN to restricted operating mode by setting FDCAN\_CCCR.ASM, which the host can only set

when both FDCAN\_CCCR.CCE and FDCAN\_CCCR.INIT are set to 1. FDCAN\_CCCR.ASM can be cleared by the host at any time.

When the sending processing unit cannot read data from the message RAM in time, it will automatically enter the restricted operation mode. To exit restricted operating mode, the host CPU must clear FDCAN\_CCCR.ASM.

The restricted operating mode CAN be used to accommodate applications with different CAN bit rates. In this case, the application tests for a different bitrate and exits the restricted mode of operation after receiving a valid frame.

Note: Restricted operating mode must not be used in conjunction with loopback mode (internal or external).

#### 34.2.1.6 Bus listening mode

Configure FDCAN\_CCCR.MON to 1 and set FDCAN to bus listening mode. In bus listening mode (see ISO 11898-1: 2015, 10.14 Bus monitoring), FDCAN is able to receive valid data frames and valid remote frames, but cannot initiate transmission. In this mode, FDCAN only sends recessive bits on the CAN bus, if FDCAN needs to send a recessive bit (ACK bit, overload flag, active error flag), that bit will be internally diverted to send so that FDCAN CAN listen for the recessive bit, but the CAN bus CAN remain recessive. In bus listen mode, the register FDCAN\_TXBRP remains reset.

The bus listening mode CAN be used to analyze the traffic on the CAN bus without affecting the bus by sending dominant bits. Figure 34-3 shows the connection of FDCAN\_TX and FDCAN\_RX signals to FDCAN in bus listening mode.

Figure 34-3 Pin control in bus listening mode

#### 34.2.1.7 Disable Automatic Retransmission (DAR) Mode

According to the CAN specification (see ISO 11898-1: 2015, 8.3. 4 Recovery Management), FDCAN CAN automatically retransmit frames that have failed arbitration or have been erroneously interfered during transmission. Automatic retransmission is enabled by default.

In DAR mode, all transmissions are automatically cancelled after they are initiated on the CAN bus. The send buffer send request suspend bit `FDCAN_TXBRP.TRPx` is reset after a successful send, and is also reset if the send has not started at the time of cancellation, the send has been aborted due to an arbitration failure, or an error occurs during frame sending.

- Successfully sent:
  - The corresponding send buffer sends the occurred bit `FDCAN_TXBTO.TOx` set
  - The corresponding send buffer cancellation completed bit `FDCAN_TXBCF.CFx` is not set
- Successfully sent even though cancelled:
  - The corresponding send buffer sends the occurred bit `FDCAN_TXBTO.TOx` set
  - The corresponding send buffer cancels the completed bit `FDCAN_TXBCF.CFx` set
- Arbitration failed or frame transmission was interfered:
  - The corresponding send buffer sends the occurred bit `FDCAN_TXBTO.TOx` is not set
  - The corresponding send buffer cancels the completed bit `FDCAN_TXBCF.CFx` set

If the frame is transmitted successfully and storage of the transmit event is enabled, the transmit event FIFO element is written with event type `ET = 0b10` (transmit will occur even if cancelled).

#### 34.2.1.8 Power Down (Sleep Mode)

The FDCAN can be set to power down mode through the CC control register `FDCAN_CCCR.CSR`. The `FDCAN_CCCR.CSR` bit reads to 1 as long as the clock stop request is valid.

When all pending send requests are completed, FDCAN will wait until the bus idle state is detected. After detecting the bus idle state, FDCAN sets `FDCAN_CCCR.INIT` to 1 to prevent any further CAN transmission. FDCAN then confirms that it is ready to enter the power down state by setting `FDCAN_CCCR.CSA` to 1. The registers can continue to be accessed until the module clock (control logic clock and communication clock) is turned off, but `FDCAN_CCCR.INIT` remains at 1.

Notes:

In the case of severe interference of the CAN bus, the idle state may never be reached, so FDCAN does not set `FDCAN_CCCR.INIT`. This condition can be detected by polling `FDCAN_PSR.ACT`. If the FDCAN does not enter the idle state, the software CAN write `CCCR.INIT = 1`, which will immediately stop the CAN communication of the FDCAN regardless of whether sending or receiving is in progress. To exit power-down mode, the application must turn on the module clock before resetting the CC control register flag `FDCAN_CCCR.CSR`. FDCAN will confirm that the clock is on by resetting `FDCAN_CCCR.CSA`. After that, the application CAN restart CAN communication by resetting `FDCAN_CCCR.INIT`.

#### 34.2.1.9 Test Mode

To enable write access to the FDCAN test register `FDCAN_TEST` (see section [FDCAN Test Register (`FDCAN_TEST`)]), `FDCAN_CCCR.TEST` must be set to 1 so that the test mode and test functionality can be configured.

By programming `FDCAN_TEST.TX`, the send pin `FDCAN_TX` can achieve four output functions. In addition to the default function of serial data output, the CAN sampling point signal CAN be driven to monitor the bit duration of FDCAN and CAN output a constant dominant or implicit level. The actual

value of pin FDCAN\_RX can be read from FDCAN\_TEST.RX. Both functions (FDCAN\_TEST.TX and FDCAN\_TEST.RX) CAN be used to check the physical layer of the CAN bus.

Due to the synchronization mechanism between the CAN communication clock and the control logic clock, there may be a delay of several control logic clock cycles between configuring FDCAN\_TEST.TX and pin FDCAN\_TX implementing the specified function. This also applies when the pin FDCAN\_RX is read through FDCAN\_TEST.RX.

Notes:

The test mode is limited to production testing and self-testing. Software control of the FDCAN\_TX pin interferes with all CAN protocol functions. It is not recommended to use test mode for practical applications.

#### 34.2.1.10 External loopback mode

Configure FDCAN\_TEST.LBCK to 1 and set FDCAN to external loopback mode. In loopback mode, FDCAN handles messages it sends itself as received messages and stores the messages (if they pass the receive filtering) into the receive buffer or receive FIFO. The following diagram shows the connection of the FDCAN\_TX and FDCAN\_RX pin signals to FDCAN in external loopback mode.

This mode is used for hardware self-test. In order to be protected from external influences, FDCAN ignores ACK errors in loopback mode (sampling to recessive bits in the ACK field of data frames or remote frames). In this mode, the signal output by FDCAN\_TX is internally fed back directly to the receiving processing unit, and the actual value of the FDCAN\_RX input pin is ignored. The sent message can be listened to from the pin FDCAN\_TX.

#### 34.2.1.11 Internal loopback mode

Configure FDCAN\_TEST.LBCK and FDCAN\_CCCR.MON to 1 and set FDCAN to internal loopback mode. This mode CAN be used for "Hot Selftest", that is, FDCAN CAN detect without affecting the connected running CAN system. In this mode, pin FDCAN\_RX is disconnected from FDCAN and pin FDCAN\_TX remains recessive. The following diagram shows the connection of the FDCAN\_TX and FDCAN\_RX pin signals to FDCAN in internal loopback mode.

Figure 34-4 Pin Control for Loopback Mode

### 34.2.2 Timestamp generation

FDCAN provides a 16-bit cycle counter to generate internal timestamps. The counting time unit CAN be configured to be 1 to 16 times the CAN bit time through the prescaler FDCAN\_TSCC.TCP. The counter value can be read via FDCAN\_TSCV.TCV. A write access to register FDCAN\_TSCV resets the counter to 0. When the timestamp counter loops, the interrupt flag FDCAN\_IR.TSW is set.

When a SOF (Start Of Frame) is received or transmitted, the count value is captured and stored to either the receive buffer or the timestamp portion of the receive FIFO (RXTS [15: 0]) or transmit event FIFO (TXTS [15: 0]) element.

### 34.2.3 Timeout counter

FDCAN provides a 16-bit timeout counter to indicate timeout conditions for receive FIFO, receive FIFO1, and send event FIFO. It works as a decrement counter and, like the timestamp counter, uses a prescaler controlled by FDCAN\_TSCC.TCP. The timeout counter is configured via the register FDCAN\_TOCC. The actual counter value can be read from FDCAN\_TOCV.TOC. The timeout counter starts only if FDCAN\_CCCR.INIT = 0. When FDCAN\_CCCR.INIT = 1, the timeout counter stops counting, for example, when CAN enters the Bus\_Off state.

The operating mode is selected via FDCAN\_TOCC.TOS. When operating in continuous mode, the counter starts when FDCAN\_CCCR.INIT is reset. Writing to FDCAN\_TOCV presets the counter to the value configured by FDCAN\_TOCC.TOP and continues to decrement the count.

When the timeout counter is controlled by one of the FIFOs, a null FIFO presets the counter to the value configured by FDCAN\_TOCC.TOP. After the first FIFO element is stored, the decrement count begins. Performing a write to FDCAN\_TOCV does not work.

When the counter reaches 0, the interrupt flag FDCAN\_IR.TOO is set. In continuous mode, the counter restarts immediately after reaching FDCAN\_TOCC.TOP.

Notes:

The clock signal of the timeout counter comes from the CAN core sampling point signal. Therefore, the point in time at which the timeout counter is decremented may vary due to the CAN kernel synchronization (resynchronization) mechanism. If the bit rate switching function is used in the CAN FD, the timeout counter uses different clock counts in the arbitration field and the data field.

### 34.2.4 Receiving processing

The receive processing unit controls the receive filtering, the transmission of received messages to the receive buffer or one of the receive FIFOs (of two in total), and the receive FIFO putting and getting indexes.

#### 34.2.4.1 Receive filtering

FDCAN is able to configure two sets of receive filters, one for the standard ID and the other for the extended ID. These two sets of filters may be assigned to receive buffer, receive FIFO 0, or receive FIFO 1. For receive filtering, each filter list performs a comparison starting from the 0th element until the first matching element. Receive filtering stops at the first matched element. The remaining filter elements are not evaluated for this message.

- The main features are:
  - Each filter element can be configured as

- \* ID Range Filter (Start and End Range)
- \* Filters with one or two dedicated IDs
- \* Classic filter for ID bit masking
- Each filter element can be configured to implement receive filtering or reject filtering
- Each filter element can be enabled/disabled individually
- Compare filter elements sequentially and stop execution after the first matching filter element
- Relevant configuration register bits:
  - Global filter configuration (FDCAN\_GFC)
  - Standard ID filter configuration (FDCAN\_SIDFC)
  - Extended ID filter configuration (FDCAN\_XIDFC)
  - Extended ID and Operation Mask (FDCAN\_XIDAM)
- Depending on the configuration of the filter element (SFEC/EFEC), one of the following actions is triggered when a match occurs:
  - Store received frames into receive FIFO0 or FIFO1
  - Store received frames in receive buffer
  - Reject received frames
  - Set high priority message interrupt flag FDCAN\_IR.HPM to 1
  - Set the high-priority message interrupt flag FDCAN\_IR.HPM to 1, and store the received frame in the receiving FIFO or FIF1. After receiving the complete ID, start receiving filtering. After the receive filtering is completed, if a matching receive buffer or receive FIFO is found, the message processing unit will start writing the received message data in 32 bits into the matching receive buffer or receive FIFO. If the CAN protocol controller detects an error condition, such as a CRC error, this message is discarded with the following effects:

#### **Receive buffer**

The new data flag that matches the receive buffer will not be set to 1, but the receive buffer (part of it) will be overwritten by the received data. For error types, see FDCAN\_PSR.LEC and FDCAN\_PSR.DLEC.

#### **Receive FIFO**

The put-in index that matches the receive FIFO is not updated, but the relevant receive FIFO element (part) is overwritten by the received data. For error types, see FDCAN\_PSR.LEC and FDCAN\_PSR.DLEC. If the matching receive FIFO operates in coverage mode, the boundary conditions introduced in the receive FIFO coverage mode must be considered.

Notes:

When a received message is written to one of the two receive FIFOs or written to the receive buffer, the unmatched received ID is stored independently of the filter used. The process of receiving filtering depends largely on the order of the filter elements configured.

#### **34.2.4.2 ID Range Filter**

This filter checks all received frames for match with message IDs within the range defined by SF1ID/SF2ID and EF1ID/EF2ID. When range filtering is used with extended frames, there are two possible scenarios:

- EFT = 0b00: The message ID and extension ID of the received frame are AND with the operation mask (FDCAN\_XIDAM) before the scope filter is applied
- EFT = 0b11: Extended ID and operation mask (FDCAN\_XIDAM) are not used for range filtering

#### 34.2.4.3 Dedicated ID Filter

The filter element can be configured to filter one or two specific message IDs. To filter a specific message ID, the filter elements must be configured as SF1ID = SF2ID and EF1ID = EF2ID.

#### 34.2.4.4 ID bit mask filter

ID bit masking filtering is used to filter groups of message IDs by masking certain bits of received message IDs. When performing ID bit mask filtering, SF1ID/EF1ID is used as a message ID filter and SF2ID/EF2ID is used as a filter ID Mask.

A bit of 0 in the ID mask will mask the corresponding bit of the configured ID filter, i.e., the value of the received message ID at this bit position is not compared with the value of the corresponding bit of the receive filter, only the bit of the received message ID corresponding to the mask bit of 1 is compared. If all mask bits are 1, a match will only occur if the received message ID and message ID filter are exactly the same. If all mask bits are 0, all message IDs match.

#### 34.2.4.5 Standard message ID filtering

Figure 34-5 illustrates the filtering process for standard message IDs (11-bit IDs). The chapter [Standard Message ID Filter Elements] describes the standard message ID filter elements.

Figure 34-5 Standard message ID filter path

Under the control of the Global Filter Configuration Register (FDCAN\_GFC) and the Standard ID Filter Configuration Register (FDCAN\_SIDFC), the ID, Remote Transfer Request Bit (RTR), and ID Extension Bit (IDE) of the received message are compared to the configured list of filter elements.

#### 34.2.4.6 Extended message ID filtering

Figure 34-6 illustrates the filtering process for extended message IDs (29-bit IDs). The chapter [Extended Message ID Filter Elements] introduces the extended message ID filter element.

Figure 34-6 Extended Message ID Filter Path

Under the control of the Global Filter Configuration Register (FDCAN\_GFC) and the Extended ID Filter Configuration Register (FDCAN\_XIDFC), the ID, Remote Transfer Request Bit (RTR), and ID Extension Bit (IDE) of the received message are compared to the configured list of filter elements. The extended ID and mask (FDCAN\_XIDAM) ANDs the received ID before the filter list is executed.

#### 34.2.4.7 Receive FIFO

Receive FIFO0 and receive FIFO1 can store up to 64 elements respectively (the actual number of elements is related to the message RAM capacity). The configuration of the two receiving FIFOs is done through the registers FDCAN\_RXFOC and FDCAN\_RXF1C.

Messages filtered by receive are transmitted to the receive FIFO that matches the filter element configuration. For a description of the filter mechanisms available for receive FIFO0 and receive FIFO1, see the section [Receive Filtering]. The chapter [Receive Buffer and FIFO Elements] introduces the receive buffer and FIFO elements.

To avoid receiving FIFO overflows, a receiving FIFO Watermark may be used. When the received FIFO fill level reaches the received FIFO water mark configured by `FDCAN_RXFnC.FnWM`, the interrupt flag `FDCAN_IR.RFnW` is set. When the put index and the fetch index of the receive FIFO meet, the condition that the receive FIFO is full is generated, and the flag bit `FDCAN_RXFnS.FnF` is set, and the interrupt flag bit `FDCAN_IR.RFnF` is set.

Figure 34-7 Receive FIFO State

When a message is read from a receiving FIFO, the receiving FIFO fetch index `FDCAN_RXFnS.FnGI` multiplied by the FIFO element size must be added to the start address `FDCAN_RXFnC.FnSA`.

Table 34-3 receive buffer and FIFO element size

| <code>RXESC.RBDS [2: 0]</code><br><code>RXESC.FnDS [2: 0]</code> | Data segment (bytes) | Element size (word) |
|------------------------------------------------------------------|----------------------|---------------------|
| 000                                                              | 8                    | 4                   |
| 001                                                              | 12                   | 5                   |
| 010                                                              | 16                   | 6                   |
| 011                                                              | 20                   | 7                   |
| 100                                                              | 24                   | 8                   |
| 101                                                              | 32                   | 10                  |
| 110                                                              | 48                   | 14                  |
| 111                                                              | 64                   | 18                  |

#### 34.2.4.8 Receive FIFO blocking mode

The receive FIFO blocking mode is configured by `FDCAN_RXFnC.FnOM = 0`, which is the default operating mode of the receive FIFO.

When the receive FIFO full condition is met (`FDCAN_RXFnS.FnPI = FDCAN_RXFnS.FnGI`), the flag bit `RXFnS.FnF = 1`, and the interrupt flag `FDCAN_IR.RFnF = 1`. At this point, the FDCAN does not continue to write messages to the corresponding receive FIFO unless the message is read from the corresponding receive FIFO and its fetch index has been incremented.

If a message is received when the corresponding receive FIFO is full, this message is discarded and indicates that the message is lost by `FDCAN_RXFnS.RFnL = 1`. In addition, the interrupt flag `FDCAN_IR.RFnL` is also set.

### 34.2.4.9 Receive FIFO overlay mode

The receive FIFO overlay mode is configured by `FDCAN_RXFnC.FnOM = 1`.

When the receive FIFO full condition is met (`FDCAN_RXFnS.FnPI = FDCAN_RXFnS.FnGI`), the flag bit `RXFnS.FnF = 1`. At this point, the next message received by FIFO will overwrite the earliest received message, and both put in index and get index will be added by 1.

If the receive FIFO is operating in override mode and the receive FIFO is full, the receive FIFO element should be read from at least the fetch index plus 1. This is because when the CPU is reading messages from the message RAM, there happens to be a received message being written to the message RAM, which may cause the data read by the CPU to be inconsistent with the actual, and adding an offset to the fetch index when reading data from the receive FIFO can avoid this problem. The offset depends on how quickly the CPU accesses the receiving FIFO. Figure 34-8 shows that the offset of the fetch index is 2 when reading the receive FIFO. In this case, the two messages stored in elements 1 and 2 are lost.

Figure 34-8 Receive FIFO Overflow Processing

After reading data from the receiving FIFO, the number of the last element read must be written to the receiving FIFO acknowledgement index register `FDCAN_RXFnA.FnA` so that the incremented acquisition index points to the next element. If the drop index is not increased to the receive FIFO element number, the receive FIFO full flag is reset (`FDCAN_RXFnS.FnF = 0`).

### 34.2.4.10 Dedicated receive buffer

FDCAN supports up to 64 dedicated receive buffers. The start address of the dedicated receive buffer is configured via `RXBC.RBSA`.

To use a dedicated receive buffer, the standard message ID filter element must be configured to have an `SFEC` bit of `0b111` and an `SFID2` bit of `0b00` for standard ID messages (see section [Standard message ID filter elements]); For extended ID messages, the extended message ID filter element must be configured to have an `EFEC` bit of `0b111` and an `EFID2` bit of `0b00` (see section [Extended Message ID Filter Elements]). The following table shows an example filter configuration for a dedicated receive buffer.

After received messages are accepted by the filter element, they are stored in the receive buffer in the message RAM referenced by the filter element. The storage format is the same as the format in which the FIFO element is received. In addition, the flag FDCAN\_IR.DRX (messages stored in the dedicated receive buffer) in the interrupt register is also set to 1.

Table 34-4 Receive Buffer Filter Configuration Example

| Filter element | SFID1 [10: 0]<br>EFID1 [28: 0] | SFID2 [10: 9]<br>EFID2 [10: 9] | SFID2 [5: 0]<br>EFID2 [5: 0] |
|----------------|--------------------------------|--------------------------------|------------------------------|
| 0              | ID Message 1                   | 00                             | 00 0000                      |
| 1              | ID Message 2                   | 00                             | 00 0001                      |
| 2              | ID Message 3                   | 00                             | 00 0010                      |

After the last word of the matching received message is written to the message RAM, the corresponding new data flag in registers FDCAN\_NDAT1/FDCAN\_NDAT2 is set. As long as the new data flag remains set, the corresponding receive buffer is locked so as not to be updated to a new matching message. The new data flag must be reset by the host writing 1 to the corresponding bit.

When the new data flag of the reception buffer is set, the corresponding message ID filter element will not perform reception filtering, and other filter elements will continue to perform reception filtering. Other message ID filter elements may cause the received message to be stored in another receive buffer or receive FIFO, or rejected, depending on the filter configuration.

#### 34.2.4.11 Receive buffer processing

- Reset interrupt flag FDCAN\_IR.DRX
- Read new data register
- Read messages from message RAM
- Reset new data flags for processed messages

#### 34.2.5 Send processing

The transmission processing unit processes the transmission requests of the dedicated transmission buffer, the transmission FIFO and the transmission queue. It controls the transmission of send messages to the CAN kernel, putting in and getting indexes, and sending event FIFO. Up to 32 send buffers CAN be set for message sending, and each send buffer CAN be independently configured with send mode (classic CAN mode or CAN FD mode). See section [Send Buffer Elements] for a description of the send buffer. The following table describes possible configurations for transmitting frames.

Table 34-5 Possible Configuration of Send Frame

| FDCAN_CCCR    |      | Send buffer element |               | Send a frame                 |
|---------------|------|---------------------|---------------|------------------------------|
| BRSE          | FDOE | FDF                 | BRS           |                              |
| lose sight of | 0    | lose sight of       | lose sight of | Classic CAN                  |
| 0             | 1    | 0                   | lose sight of | Classic CAN                  |
| 0             | 1    | 1                   | lose sight of | FD without switching bitrate |
| 1             | 1    | 0                   | lose sight of | Classic CAN                  |
| 1             | 1    | 1                   | 0             | FD without switching bitrate |
| 1             | 1    | 1                   | 1             | FD of switching bitrate      |

Notes:

AUTOSAR requires at least three send queue buffers and supports send cancellation.

When the send buffer request pending register FDCAN\_TXBRP is updated, the send processing unit initiates a send scan to check for the highest priority pending send request (the send buffer with the

smallest message ID). FDCAN\_TXBRP is updated on the condition that a transmission buffer is completed, or the host adds a transmission request by writing FDCAN\_TXBAR, or the host cancels a pending transmission by writing FDCAN\_TXBCR.

#### 34.2.5.1 Send pause

The transmission suspension function is used in a CAN system in which the CAN message ID is (permanently) specified as a specific value and cannot be easily changed. The CAN arbitration priority of these message IDs may be higher than other defined messages, and their relative arbitration priority should be reversed in a specific application. This may lead to a situation in which one ECU bursts a plurality of CAN messages of higher arbitration priority and another ECU CAN message of lower arbitration priority is delayed.

For example, if the CAN ECU-1 has this feature enabled and its application software requests four messages to be sent, after successful sending of the first message, it will wait for a CAN bit time for both buses to be idle before allowing the next requested message to begin sending. If other ECUs have pending messages, they will start sending them during idle time and do not need to arbitrate with the next message of ECU-1. Upon receiving the message, the ECU-1 may start the next transmission immediately after the received message releases the CAN bus.

This functionality is controlled via FDCAN\_CCCR.TXP. If this is bit, after each successful message transmission, FDCAN will pause for two CAN bits before starting the next transmission. In this way, messages can be sent even if the ID priority of other nodes in the network is lower. This feature is disabled by default (FDCAN\_CCCR.TXP = 0). This feature makes multiple messages from a single node burst sparse, avoiding ECUs sending lower priority messages from applications mistakenly thinking they are requesting too many transmissions.

#### 34.2.5.2 Dedicated send buffer

The dedicated send buffer can send messages completely under the control of the host CPU. Each dedicated send buffer is configured with a specific message ID. If multiple send buffers are configured with the same message ID, the messages in the send buffer with the smallest number are sent first, and these send buffers should be requested in ascending order, that is, the smallest send buffer number is requested first, or simultaneously via a single write FDCAN\_TXBAR.

If there is an update to the message in the buffer, it is sent by setting FDCAN\_TXBAR.ARn request. The requested message will be arbitrated internally with the message in the sending FIFO or sending queue according to the message ID, then externally with the message on the CAN bus, and finally sent out according to the arbitration result.

The allocated dedicated send buffer element size in the message RAM is several 32-bit words (4 bytes). Therefore, the start address of the dedicated send buffer in the message RAM is calculated by multiplying the send buffer index (0 ~ 31) by the element size (word), then multiplying it by 4 (converted to bytes), and then adding it to FDCAN\_TXBC.TBSA.

Table 34-6 send buffer, FIFO (queue) element size

| TXESC.TBDS2 [2: 0] | Data segment (bytes) | Element size (word) |
|--------------------|----------------------|---------------------|
| 000                | 8                    | 4                   |
| 001                | 12                   | 5                   |
| 010                | 16                   | 6                   |
| 011                | 20                   | 7                   |

|     |    |    |
|-----|----|----|
| 100 | 24 | 8  |
| 101 | 32 | 10 |
| 110 | 48 | 14 |
| 111 | 64 | 18 |

### 34.2.5.3 Send FIFO

The transmission FIFO mode is achieved by configuring FDCAN\_TXBC.TFQM to 0. The message stored in the transmit FIFO is transmitted from the message pointed to by the fetch index FDCAN\_TXFQS.TFGI. After each send, the fetch index is cyclically incremented until the send FIFO is empty. Send FIFO sends messages from different send buffers but with the same ID in the order in which the messages were written. FDCAN calculates the difference between the acquired index and the put index to obtain the number of available (idle) transmitted FIFO elements (TXFQS.TFFL).

The new message must be written to be placed in the send FIFO at the beginning of the send buffer pointed to by the index FDCAN\_TXFQS.TFQPI. Adding a send request increments the put-in index to the next free send FIFO element. When the drop index meets the fetch index, it indicates that the send FIFO is full (FDCAN\_TXFQS.TFQF = 1). In this case, you should not continue to write messages to the sending FIFO until the next message has been sent and the fetch index is incremented.

If a single message is added to the transmission FIFO, the transmission is requested by writing 1 to the FDCAN\_TXBAR bit corresponding to the index of the transmission FIFO.

If multiple (assuming n) messages are added to the send FIFO, they are written to n consecutive send buffers starting with the drop-in index. It is then sent via the FDCAN\_TXBAR request, putting in the index cyclically incremented by n. The number of send buffers requested to be sent should not exceed the number of free send buffers indicated by the send FIFO idle level (FDCAN\_TXFQS.TFFL).

If the send request for the send buffer pointed to by the fetch index has been canceled, the fetch index is incremented to the next send buffer with a send request pending and the send FIFO idle level (FDCAN\_TXFQS.TFFL) is recalculated. If you cancel the sending of any other send buffer, the fetch index and FIFO idle level remain unchanged.

The allocated transmit FIFO element size in the message RAM is several 32-bit words (4 bytes). Therefore, the start address of the next available (idle) transmit FIFO is calculated by multiplying the put-in index FDCAN\_TXFQS.TFQPI (0-31) by the element size (word), multiplying it by 4, and then adding it to FDCAN\_TXBC.TBSA.

### 34.2.5.4 Send Queue

Send queue mode is achieved by configuring FDCAN\_TXBC.TFQM to 1. Messages stored in the send queue are sent first from the message ID with the smallest (highest priority). If multiple send queues are configured with the same message ID, if multiple send queues are configured with the same message ID, the send order cannot be predicted because the send order is related to the number of the send queues in which the message is stored, and the number of these send queues depends on the state currently put into the index.

The new message must be written into the send buffer pointed to by the index FDCAN\_TXFQS.TFQPI. The drop-in index always points to the least numbered free buffer in the send queue. If the send queue is full (FDCAN\_TXFQS.TFQF = 1), the put-in index is invalid and messages should not continue to be

written to the send queue until at least one requested message has been issued or a pending send request has been canceled.

The application can use the register FDCAN\_TXBRP instead of putting the index, and can put the message into any send buffer where there is no pending send request.

The allocated send queue buffer element size in message RAM is several 32-bit words (4 bytes). Therefore, the start address of the next available (free) send queue buffer is calculated by multiplying the put-in index FDCAN\_TXFQS.TFQPI (0-31) by the element size (word), multiplying it by 4, and then adding it to FDCAN\_TXBC.TBSA.

#### 34.2.5.5 Mixing dedicated send buffer and send FIFO

In this case, the send buffer in the message RAM is divided into a set of dedicated send buffers and a send FIFO. The number of dedicated send buffers is configured via FDCAN\_TXBC.NDTB. The number of transmit buffers allocated to the transmit FIFO is configured by FDCAN\_TXBC.TFQS. If FDCAN\_TXBC.TFQS is configured to 0, only the dedicated send buffer will be used.

Figure 34-9 Example of mixed configuration of dedicated send buffer and send FIFO

Send priority:

- Scan all dedicated send buffers with activated send requests and the send FIFO buffer with the earliest pending send requests (the buffer pointed to by FDCAN\_TXEFS.TFGI)
- The buffer with the smallest message ID has the highest priority, and the message of this buffer will be sent next time

#### 34.2.5.6 Mixing dedicated send buffers and send queues

In this case, the send buffer in the message RAM is divided into a set of dedicated send buffers and a send queue. The number of dedicated send buffers is configured via FDCAN\_TXBC.NDTB. The number of send queue buffers is configured via FDCAN\_TXBC.TFQS. If FDCAN\_TXBC.TFQS is configured to 0, only the dedicated send buffer will be used.

Figure 34-10 Example of mixed configuration of dedicated send buffer and send queue

Send priority:

- Scan all dedicated send buffers and send queue buffers where send requests are activated
- The sending buffer with the smallest message ID has the highest priority, and the message of this buffer will be sent next time

#### 34.2.5.7 Send Cancel

FDCAN supports the send cancel function. This feature is particularly suitable for gateway applications and AUTOSAR-based applications. To cancel a send request for the dedicated send buffer or send queue buffer, the host must write 1 to the corresponding bit in register FDCAN\_TXBCR (the bit corresponding to the send buffer index). Send Cancel does not apply to Send FIFO mode.

After successful cancellation, the corresponding bit of register FDCAN\_TXBCF is set to 1.

If a request is made to cancel the transmission during the buffer transmission, the corresponding bit of FDCAN\_TXBRP will remain set to 1 as long as the transmission is in progress. If the transmission is successful, the corresponding bits of FDCAN\_TXBTO and FDCAN\_TXBCF are set to 1. If the transmission is unsuccessful, the transmission will not be repeated, only the corresponding position bit of FDCAN\_TXBCF will be transferred.

Notes:

If a pending transmission is cancelled immediately before transmission is started, even if another message is pending in that node, the cancellation will be followed by a short window during which no transmission will be started. In this way, another node can send messages that may have a lower priority than the second message in that node.

#### 34.2.5.8 Send event handling

FDCAN supports the handling of send events with send event FIFO. After FDCAN sends a message on the CAN bus, the message ID and timestamp are stored in the Send Event FIFO element. In order to associate the send event with the send event FIFO element, the message tag in the sent send buffer is copied into the send event FIFO element.

The Send Event FIFO can be configured with up to 32 elements, and the chapter [Send Event FIFO Elements] describes the Send Event FIFO elements.

The purpose of the transmit event FIFO is to separate the processing of the transmit status information from the processing of the transmit messages, that is, let the transmit buffer only hold the messages to be sent, and store the transmit status separately in the transmit event FIFO. This has advantages, especially when dealing with dynamically managed send queues, where the send buffer can be used for new messages immediately after successful sending. Before rewriting the transmission buffer, it is not necessary to save the transmission status information of the transmission buffer.

When `FDCAN_IR.TEFF` indicates that the transmit event FIFO is full, writing of elements to the transmit event FIFO will not continue until at least one element has been read and the transmit event FIFO fetch index has been incremented. If a send event occurs while the send event FIFO is full, this event is discarded and the interrupt flag `FDCAN_IR.TEFL` is set.

To avoid the Send Event FIFO overflow, you can use the Send Event FIFO watermark. The interrupt flag `FDCAN_IR.TEFW` is set when the transmit event FIFO fill quantity reaches the transmit event FIFO water mark configured by `TXEFC.EFWM`.

When reading data from the send event FIFO, you must multiply the send event FIFO fetch index `TXEFS.EFGI` by 2 (the send event FIFO element size is two words), multiply it by 4, and then add it to the send event FIFO start address `TXEFC.EFSA` to get the address where the target data is located.

#### 34.2.6 FIFO acknowledgement processing

The acquisition indexes of receive FIFO, receive FIFO1 and send event FIFO are controlled by writing the corresponding FIFO acknowledgement index registers, see chapters [FDCAN receive FIFO0 acknowledgement register (`FDCAN_RXF0A`)], [FDCAN receive FIFO1 acknowledgement register (`FDCAN_RXF1A`)] and [FDCAN send event FIFO acknowledgement register (`FDCAN_TXEFA`)]. Writing to the FIFO acknowledgement index sets the FIFO acquisition index to the FIFO acknowledgement index plus 1, which in turn updates the FIFO padding level. There are two use cases:

1. If only one element (the element pointed to by the fetch index) is read from the FIFO, the fetch index value should be written to the FIFO acknowledgement index register.
2. If a sequence of elements has been read from the FIFO, the FIFO acquisition index can be updated only by writing the index value of the last element into the FIFO confirmation index register at the end of the sequence read.

Since the CPU has free access to the message RAM of the FDCAN, special care is needed when reading FIFO elements in any order (regardless of the fetch index), especially when reading high priority messages from one of the two receiving FIFOs. In this case, no write operation should be done to the FIFO acknowledgement index register, otherwise it will cause the fetch index to point to the wrong location, and it will also change the FIFO padding level, and some of the earlier FIFO elements may be lost.

Notes:

The application must ensure that the value written to the FIFO acknowledgement index register is correct, and FDCAN will not check whether the value is correct.

### 34.2.7 Message RAM

#### 34.2.7.1 Message RAM configuration

The width of the message RAM is 32 bits. The FDCAN module can allocate up to 212 words in the message RAM as shown in the figure below. In practical applications, it is not required that all parts be configured, and there is no limitation on the order between parts.

Figure 34-11 Message RAM Configuration

When FDCAN accesses message RAM, it needs to be addressed by 32-bit aligned addresses, not byte aligned addresses. The configurable start address is a 32-bit word address, i.e. only 15 to 2 bits of the address are evaluated, ignoring the two least significant bits.

Notes:

FDCAN does not check whether there are errors in the configuration of message RAM, so you must pay more attention when configuring the start address of different parts and the number of elements in each part to avoid data intrusion or loss.

#### 34.2.7.2 Receive buffer and FIFO element

Up to 2 receive FIFO/receive buffers can be configured in the message RAM. Each receive FIFO/receive buffer can be configured to store up to 3 messages. The structure of the receiving buffer and the receiving FIFO element is shown in the following table. Please see the following table for related instructions. The element size can be configured through the register FDCAN\_RXESC, and the data segment of the CAN FD message can be up to 64 bytes.

Table 34-7 receive buffer and FIFO element

| Bit | 31 24      |             |     |            | 23 16        |     |     |            | 15 8         |  | 7 0          |  |

### 34.2.7.3 Send buffer element

The send buffer can be configured as a dedicated send buffer and a send FIFO (or queue). If the transmit buffer is shared by the dedicated transmit buffer and the transmit FIFO (or queue), the dedicated transmit buffer is at the beginning of the transmit buffer, followed by the transmit FIFO (or queue). The transmit processing unit evaluates the transmit buffer configurations FDCAN\_TXBC.TFQS and FDCAN\_TXBC.NDTB to distinguish between a dedicated transmit buffer and a transmit FIFO (queue). The structure of the send buffer elements is shown in the following table. Please see the following

table for relevant instructions. The element size can be configured through the register FDCAN\_TXESC, and the data segment of the CAN FD message can be up to 64 bytes.

#### 34.2.7.4 Send Event FIFO Element

Each element stores information related to the sent message. By reading the send event FIFO, the host CPU obtains this information in the order in which the messages were sent. Information on the status of the transmit event FIFO can be obtained from the register FDCAN\_TXEFS. The structure of the Send Event FIFO element is shown in the following table. Please see the following table for related instructions.

E1A: When FDCAN\_CCCR.WMM = 0, E1A.TXTS [15: 0] holds a 16-bit timestamp generated by the internal timestamp logic of FDCAN.

E1B: When the 16-bit wide message flag is enabled (FDCAN\_CCCR.WMM = 1), E1B. MM [15: 8] is the upper 8 bits of the wide message flag.

Table 34-11 Send Event FIFO Element

### 34.2.7.5 Standard Message ID Filter Element

Up to 128 filter elements (1 word in size each) can be configured for an 11-bit standard ID. Its address is the filter element index (0 ~ 127) multiplied by 4 (converted to bytes), plus the starting address FDCAN\_SIDFC.FLSSA. The structure of the standard message ID element is shown in the following table. Please see the following table for related descriptions.

Table 34-13 Standard Message ID Filter Element

| Bit | 31 24                  | 23 16         | 15 8 | 7 0           |

### 34.2.7.6 Extended Message ID Filter Element

Up to 64 filter elements (2 words in size each) can be configured for a 29-bit extended ID. When accessing an extended message ID filter element, its address is the filter element index (0-63) multiplied by 2, then multiplied by 4 (converted to bytes), and then the starting address FDCAN\_XIDFC.FLESA is added. The structure of the extended message ID element is shown in the following table. Please see the following table for related instructions.

Table 34-15 Extension Message ID Filter Element

| Bit | 31 24       | 23 16 | 15 8          | 7 0 |
|-----|-------------|-------|---------------|-----|
| F0  | EFEC [2: 0] |       | EFID1 [28: 0] |     |
| F1  | EFT [1: 0]  | Res   | EFID2 [28: 0] |     |

Table 34-16 Extension Message ID filter element description

| Bitfield    | mark          | Description                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                 |

| 31: 0 | ETV  | R   | 0x87        | Byte order test value |

#### 34.3.2 FDCAN Data Bit Time and Prescalation Register (FDCAN\_DBTP), Address = 0x0C

Address offset: 0x00C

Reset value: 0x00000A33

Write access to this register can only be made if both the FDCAN\_CCCR.CCE and FDCAN\_CCCR.INIT bits are set.

The programmable range of CAN bit time is from 4 to 49 time slices (Time quanta, tq). The CAN time slice is programmable from 1 to 32 FDCAN communication clock cycles (Minimum time quantum, mtq).  $tq = (DBRP + 1) mtq$ .

DTSEG1 is the sum of Prop\_Seg and Phase\_Seg1. DTSEG2 is Phase\_Seg2.

Therefore, the length of the bit time is either (program value)  $[DTSEG1 + DTSEG2 + 3] tq$  or (function value)  $[Sync\_Seg + Prop\_Seg + Phase\_Seg1 + Phase\_Seg2] tq$ .

The information processing time (IPT) is zero, which means that the next bit of data is available at the first clock edge after the sampling point.

Note: When the FDCAN communication clock is 8MHz, the reset value 0x0000 0A33 configures the bitrate of the FDCAN data segment to 500Kbps. The CAN FD data segment bit rate configured by DBTP cannot be less than the arbitration segment bit rate configured by NBTP.

### 34.3.3 FDCAN Test Register (FDCAN\_TEST), Address = 0x10

Address offset: 0x010

Reset value: 0x000000X0 (the reset value of bit 7 is determined by the actual level of the FDCAN\_RX pin)

Write access to this test register can only be made if the FDCAN\_CCCR.TEST bit is set to 1. When the FDCAN\_CCCR.TEST bit is cleared, all test register functions are set to their reset value.

Loopback mode and software control FDCAN\_TX pin belong to hardware test mode. TX may interfere with message transmission on the CAN bus when configured to not 0b00.

#### 34.3.4 FDCAN RAM Watchdog Register (FDCAN\_RWD), Address = 0x14

Address offset: 0x014

Reset value: 0x0000 0000

The RAM watchdog monitors the READY signal output of the message RAM. Access to message RAM starts a message RAM watchdog counter whose starting value is configured by the FDCAN\_RWD.WDC bit.

This counter reloads the value of FDCAN\_RWD.WDC when the message RAM indicates that the access has successfully completed by activating its READY signal output. If the message RAM does not respond before the counter is decremented to 0, the counter will stop counting and will interrupt the flag FDCAN\_IR.WDI position 1. The RAM watchdog counter is counted by the FDCAN control logic clock.

Therefore, before resetting the INIT value, verify that the previous setting value has indeed been written. |

### 34.3.6 FDCAN Nominal Bit Time and Prescalation Register (FDCAN\_NBTP), Address = 0x1C

Address offset: 0x01C

Reset value: 0x0600 0A03

Write access to this register can only be made if both the FDCAN\_CCCR.CCE and FDCAN\_CCR.INIT bits are set to

1. The programmable range of CAN nominal bit time is 4 to 385 time slices (Time quanta, tq). The CAN time slice is programmable from 1 to 512 FDCAN communication clock cycles (Minimum time quantum, mtq).  $tq = (NBRP + 1) mtq$ .

NTSEG1 is the sum of Prop\_Seg and Phase\_Seg1. NTSEG2 is Phase\_Seg2.

Therefore, the length of the bit time is either (program value)  $[NTSEG1 + NTSEG2 + 3] tq$  or (function value)  $[Sync\_Seg + Prop\_Seg + Phase\_Seg1 + Phase\_Seg2] tq$ .

The information processing time (IPT) is zero, which means that the next bit of data is available at the first clock edge after the sampling point.

### 34.3.7 FDCAN Timestamp Counter Configuration Register (FDCAN\_TSCC), Address = 0x20

Address offset: 0x020

Reset value: 0x0000 0000

This register is used to configure an internal 16-bit timestamp counter. For an introduction to internal timestamp processing, please refer to chapter [Timestamp Generation].

| 2: 0 | LEC [2: 0] | R | 0 | <p>Last error code</p> <p>0: No Error. No errors have occurred since successful reception or transmission to reset the LEC.</p> <p>1: Stuff Error. In the received message, there are more than 5 identical ones in a certain part</p> <p>Bits, this situation is not allowed.</p> <p>2: Form Error. There is a format error in the fixed format portion of the received frame.</p> <p>3: ACK Error. The message sent by FDCAN is not acknowledged by other nodes.</p> <p>4: Bit1 Error. In the process of sending a message (except for the arbitration segment), the device wants to send a hidden</p> <p>Sex level (logic value 1), but the monitored bus level is dominant (logic value 0).</p> <p>5: Bit0 Error. During the transmission of the message (including ACK bit, active error flag, overload</p> <p>Flag), the device wants to send an explicit level (logical value of data or ID 0), but the detected bus level is</p> <p>Implicit (logical value 1). During bus Bus_Off recovery, each time an 11-bit recessive bit sequence is detected, it is set</p> <p>Set to this state. This allows the CPU to monitor the progress of the bus recovery sequence (indicating that the bus is not stuck in an explicit state</p> <p>Or persistently disturbed).</p> <p>6: CRC Error. There is an error in the CRC of the received message. CRC received and data received with</p> <p>The calculated CRC does not match.</p> <p>7: No Change. Any read access to the protocol status register reinitializes the LEC to 7.</p> <p>When the LEC displays a value of 7, it indicates that the protocol status register has not been detected since the last read access by the CPU</p> <p>CAN bus events.</p> <p>Notes:</p> <p>1. When the CAN FD frame with the BRS flag set has reached the data segment, the next CAN event (error or valid frame) will be displayed in the DLEC instead of the LEC. An error with a fixed padding bit in the CAN FD CRC sequence will appear as a Form Error instead of a Stuff Error.</p> <p>2. Bus_Off recovery sequence (refer to ISO11898-1: 2015) cannot be set or cleared</p> <p>FDCAN_CCCR.INIT to shorten. If the device enters the Bus_Off state, it automatically sets FDCAN_CCCR.INIT, stopping all bus activity.</p> <p>Once FDCAN_CCCR.INIT is cleared by the CPU, the device will wait</p> |

|  |  |  |  |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |

|  |  |  |  | for 129 bus idles (129 * 11 consecutive recessive bits) before resuming normal operation. At the end of the Bus_Off recovery sequence, the error management counter is reset. During the waiting period after clearing FDCAN_CCCR.INIT, each time an 11-bit recessive sequence is detected, a Bit0 error code is written to FDCAN_PSR.LEC, enabling the CPU to check whether the CAN bus is dominant or continuously disturbed at any time, and to monitor the Bus_Off recovery sequence. FDCAN_ECR.REC was used to count these sequences.<br>3. During byte operation, reading byte 0 of the register will set LEC to 0b111, and reading byte 3/2/1 has no effect. |

| 6: 0   | TDCF [6: 0] | RW  | 0           | Transmitter delay compensation filter window width<br>Define the minimum value of the SSP position. For measurements of transmitter delay, the dominant edge on the FDCAN_RX pin that causes the SSP position to advance will be ignored. This function is enabled when the TDCF setting is greater than the TDCO. The effective setting value is 0 ~ 127mtq. |

### 34.3.14 FDCAN interrupt register (FDCAN\_IR), Address = 0x50

Address offset: 0x050

Reset value: 0x0000 0000

When one of the conditions in the following list is detected, the corresponding flag bit is set. Remains set until the host clears the flag bit to zero. All flag bits are cleared by writing 1, and writing 0 has no effect. A hard reset will clear the registers. Whether an interrupt is generated is controlled by the register FDCAN\_IE; Which interrupt line generates an interrupt is controlled by the register FDCAN\_ILS.

### 34.3.15 FDCAN interrupt enable register (FDCAN\_IE), Address = 0x54

Address offset: 0x054

Reset value: 0x0000 0000

The setting in the interrupt enable register determines which state changes in the interrupt register (FDCAN\_IR) are indicated on the interrupt line.

### 34.3.16 FDCAN interrupt line select register (FDCAN\_ILS), Address = 0x58

Address offset: 0x058

Reset value: 0x0000 0000

An interrupt line select register that assigns an interrupt generated by a specific interrupt flag in the interrupt register (FDCAN\_IR) to one of the two interrupt lines. To generate an interrupt, the corresponding interrupt lines must be enabled via FDCAN\_ILE.EINT0 and FDCAN\_ILE.EINT1.

### 34.3.22 FDCAN High Priority Message Status Register (FDCAN\_HPMS), Address = 0x94

Address offset: 0x094

Reset value: 0x0000 0000

A message ID filter element configured to generate priority events that updates this register every time it matches.

This can be used to monitor the status of received high-priority messages and provide quick access to these messages.

This action sets the receive FIFO1 fetch index FDCAN_RXF1S.F1GI to F1AI plus 1 and updates the FIFO1 fill level FDCAN_RXF1S.F1FL |

### 34.3.32 FDCAN receive buffer and FIFO element size configuration register (FDCAN\_RXESC), Address = 0xBC

Address offset: 0x0BC

Reset value: 0x0000 0000

Configure the number of bytes of data for the receive buffer and the receive FIFO element. Data segments larger than 8 bytes are only available in CAN FD mode.

Note:

The sum of TFQS and NDTB shall not be greater than 32. FDCAN does not monitor this setting error. The send buffer portion of the message RAM starts with a dedicated send buffer.

### 34.3.34 FDCAN send FIFO/queue status register (FDCAN\_TXFQS), Address = 0xC4

Address offset: 0x0C4

Reset value: 0x0000 0000

The status of the transmit FIFO or queue is related to the pending transmit request in the register FDCAN\_TXBRP. As a result, the effect of adding or canceling requests may be delayed due to a running send scan (TXBRP has not been updated yet).

| 7: 6  | Reserved     | -   | 0           | -                                                                                                                                                                           |
| 5: 0  | TFFL [5: 0]  | R   | 0           | Send FIFO Idle Level<br>Number of consecutively idle transmit FIFO elements from TFGI, range 0-32. If configured to send queue mode (FDCAN_TXBC.TFQM = 1), this bit reads 0 |

Note: When the dedicated transmit buffer is configured in combination with the transmit FIFO or transmit queue, the put index and get index refer to the transmit buffer number from the first dedicated transmit buffer.

For example, for a combined configuration with 12 dedicated send buffers and 20 send FIFO buffers, put index 15 to point to the 4th buffer of the send FIFO.

### 34.3.35 FDCAN Send Buffer Element Size Configuration Register (FDCAN\_TXESC), Address = 0xC8

Address offset: 0x0C8

Reset value: 0x0000 0000

Configures the number of bytes of data to send buffer elements. Data segments larger than 8 bytes are only available in CAN FD mode.

|------|-------------|-----|-------------|----------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 31:0 | TRP [31: 0] | R   | 0           | <p>Send request pending flag</p> <p>Each send buffer has its own send request suspend bit. These bits are set through the register FDCAN_TXBAR; Resets after the sending of the request has been completed, or the sending of the request has been canceled through the register FDCAN_TXBCR.</p> <p>Only the TXBRP bit corresponding to the transmit buffer configured by FDCAN_TXBC will be set. A send scan is initiated after the TXBRP position bit (see section [Send Processing]) to check for the highest priority pending send requests (i.e., the send buffer with the smallest message ID). Cancelling the send request resets the corresponding TXBRP bit. If the transmission has already started when the request is cancelled, the TXBRP bit is reset at the end of the transmission regardless of whether the transmission is successful or not. After the TXBRP bit is reset, the corresponding cancel request bit will also be reset immediately.</p> <p>After the cancellation is requested, the following conditions indicate through the register FDCAN_TXBCF that the cancellation is complete:</p> <ul style="list-style-type: none"> <li>• After successful transmission and the corresponding FDCAN_TXBTO position bit</li> <li>• Send has not started when cancelled</li> <li>• Send aborted due to arbitration failure</li> <li>• Error occurred during frame transmission</li> </ul> <p>In DAR mode, all sends are automatically cancelled after failure. For all failed transmissions, the corresponding FDCAN_TXBCF bit will be set.</p> <p>0: No send request pending<br/>1: Send request pending</p> <p>Note: The TXBRP bits set during the transmission scan are ignored during this transmission scan. During this period, if these transmissions are requested to be cancelled, the transmissions are immediately cancelled and the corresponding TXBRP bits are reset.</p> |

### 34.3.37 FDCAN send buffer add request register (FDCAN\_TXBAR), Address = 0xD0

Address offset: 0x0D0

Reset value: 0x0000 0000

Configures the number of bytes of data to send buffer elements. Data segments larger than 8 bytes are only available in CAN FD mode.

## 35. Serial Peripheral Interface (SPI/I2S)

### 35.1 Overview

The SPI interface may be configured to support the SPI protocol or to support the I2S audio protocol. The SPI interface works in SPI mode by default, and functions can be switched from SPI mode to I2S mode through software.

Figure 35-1 SPI block diagram

The Serial Peripheral Interface (SPI) allows the chip to communicate with external devices in half/full duplex, synchronous, serial mode. The interface can be configured as master and in this case it provides the serial clock (SCK) to the external slave device. The interface is also capable of operating in multimaster configuration. It can be used for a variety of purposes, including two-wire simplex synchronous transmission using one bi-directional data line, and reliable communication with CRC verification. I2S is also a 3-pin synchronous serial interface communication protocol. It supports four audio standards, including the Philips I2S standard, the MSB and LSB alignment standards, and the PCM standard. It is in half-duplex communication and can work in master and slave 2 modes. When it acts as a master device, it provides a clock signal to an external slave device through an interface.

#### 35.1.1 SPI features

- 3-wire full-duplex simultaneous transmission
- 2-wire half-duplex synchronous transmission (with bidirectional data line)
- 2-wire simplex synchronous transmission (no bidirectional data line)
- 8 or 16-bit transport frame format selection
- Master or Slave Operation
- Support multi-master mode

- 8 main mode baud rate prescaling coefficients (up to  $f_{PCLK}/2$ )
- Slave mode frequency (up to  $f_{PCLK}/2$ )
- Both Master and Slave modes can be managed by software or hardware NSS: dynamic change of Master/Slave operating mode
- Programmable clock polarity and phase
- Programmable data order, MSB first or LSB first
- Dedicated transmit and receive flags that can trigger interrupts
- SPI bus busy status flag
- Hardware CRC feature for reliable communication
  - In transmit mode, the CRC value can be transmitted as last byte
  - In full-duplex mode, the last received byte is automatically checked for CRC.
- Primary mode failure, overload, and CRC error flags that can trigger interrupts
- Two embedded Rx and Tx FIFOs with a depth of 4 and a width of 16 bits (8 bits when the data frame is set to 8 bits) with DMA functionality

### 35.1.2 I2S features

- Half-duplex communication (only transmitter or receiver)
- Master or slave operations
- 8-bit linear programmable prescaler for accurate audio sampling frequency (8-192 kHz)
- Data format may be 16-bit, 24-bit or 32-bit
- The audio channel fixed packet frame is 16-bit (16-bit data frame) or 32-bit (16, 24 or 32-bit data frame)
- Programmable clock polarity (steady state)
- Underflow flag in slave transmit mode and Overflow flag in master/slave receive mode
- 16-bit register for transmission and reception with one data register for both channel sides
- Support I2S protocols:
  - I2S Philips Standard
  - MSB Alignment Standard (Left Alignment)-LSB Alignment Standard (Right Alignment)-PCM Standard (16-bit channel frame with long or short frame synchronization or 16-bit data frame expansion to 32-bit channel frame)
- Data direction is always MSB first
- DMA capability for transmission and reception
- Master clock may be output to drive an external audio component. Ratio is fixed at  $256 \times FS$  (where FS is the audio sampling frequency)

## 35.2 SPI functional description

### 35.2.1 Communications between one master and one slave

The SPI allows the MCU to communicate using different configurations, depending on the device targeted and the application requirements. These configurations use 2 or 3 wires (with software NSS management) or 4 wires (with hardware NSS management).

### 35.2.1.1 Full-duplex communication

By default, the SPI is configured for full-duplex communication. In this configuration, the shift registers of the master and slave are linked using two unidirectional lines between the MOSI and the MISO pins. During SPI communication, data is shifted synchronously on the SCK clock edges provided by the master. The master transmits the data to be sent to the slave via the MOSI line and receives data from the slave via the MISO line. When the transmission of the data frame is completed, the information exchange between the master and the slave is terminated.

Figure 35-2 Full-duplex single master/ single slave application

### 35.2.1.2 Half-duplex communication

The SPI can communicate in half-duplex mode by setting the BIDIMODE bit in the SPI\_CR1 register. In this configuration, one single cross connection line is used to link the shift registers of the master and slave together. During this communication, the data is synchronously shifted between the shift registers on the SCK clock edge in the transfer direction selected reciprocally by both master and slave with the BDIOE bit in their SPI\_CR1 registers. In this configuration, the MISO of the master and the MOSI of the slave may be released as general-purpose ports for use by other applications.

Figure 35-3 Half-duplex single master/ single slave application

The NSS may be used for hardware control between the master and the slave. NSS simplex communication can also be controlled using software.

The SPI can communicate in simplex mode by setting the SPI in transmit-only or in receive-only using the RXONLY bit in the SPI\_CR1 register. In this configuration, only one line is used for the transfer between the shift registers of the master and slave. In this configuration, the MISO of the master and the MOSI of the slave may be released as general-purpose ports for use by other applications.

- **Receive-only mode (RXONLY=1):** The application can disable the SPI output function by setting the RXONLY bit. In slave configuration, the MISO output is disabled and the pin can be used as a GPIO. The slave continues to receive data from the MOSI pin while its slave select signal is active. In the master configuration, the MOSI output is disabled and the pin can be used as a GPIO. The clock signal is generated continuously as long as the SPI is enabled. The only way to stop the clock is to clear the RXONLY bit or the SPE bit and wait until the incoming pattern from the MISO pin is finished.
- **Transmit-only mode (RXONLY=0):** The configuration settings are the same as for full-duplex. An unused port may be used as a standard GPIO.

Figure 35-4 Single master/ single slave application

(master in transmit-only/slave in receive-only mode)

- (1) NSS can be used for hardware control between the master and the slave. NSS optional software control.
- (2) In the standard transmit-only mode, all events related to transmission and reception must be ignored.
- (3) In this configuration, both MISO pins can be used as GPIOs.

Note: Set BIDIMODE bidirectional mode, any simplex communication can be changed to half-duplex communication.

### 35.2.2 Multi-slave communication

In an application scenario with two or more independent slaves, the host uses GPIO to control NSS to manage the slaves. The master must select a slave by pulling down the connected slave NSS. When this is done, communication between the master and the selected slave is established.

NSS pin is not used on master side at this configuration. It has to be managed internally (SSM=1, SSI=1) to prevent any MODF error.

### 35.2.3 Multi-master communication

The connection of more than two SPI nodes working at this mode is impossible as only one node can apply its output on a common data line at time.

If both nodes give a control request at the same time, a bus conflict will generate a MODF event.

Figure 35-6 Multi-master application

### 35.2.4 Slave Select (NSS) Pin Management

In slave mode, the NSS works as a standard “chip select” input and lets the slave communicate with the master. In master mode, NSS can be used either as output or input. When used as input, it prevents bus collisions for multiple masters, and when used as output, it can drive the slave select pin of a single slave.

Through the SSM bit of the SPI\_CR1 register, you can choose hardware or software for slave management:

- Software NSS management (SSM = 1): in this configuration, slave select information is driven internally by the SSI bit value in register SPI\_CR1. The external NSS pin is free for other application uses.
- Hardware NSS management (SSM = 0): in this case, there are two possible configurations.
  - 1) NSS output enabled (SSM = 0, SSOE = 1): This configuration is used only when the device operates in master mode. The NSS pin is managed by the hardware. The NSS signal is driven low as soon as the SPI is enabled in master mode (SPE=1), and is kept low until the SPI is disabled (SPE =0). The SPI cannot work in multimaster configuration with this NSS setting.
  - 2) NSS Output Disabled (SSM = 0, SSOE = 0): This configuration allows multi-host communication if the MCU is the host on the bus. If the NSS pin is pulled low at this time, the SPI enters the master mode default state and is automatically configured to slave mode. In slave mode, the NSS pin works as a standard “chip select” input and the slave is selected while NSS line is at low level.

Figure 35-7 Hardware/software slave select management

### 35.2.5 Communication formats

During SPI communication, receive and transmit operations are performed simultaneously. The serial clock (SCK) synchronizes the shifting and sampling of the information on the data lines. The communication format depends on the clock phase, the clock polarity and the data frame format. To be able to communicate together, the master and slave devices must follow the same communication format.

#### 35.2.5.1 Clock phase and polarity controls

Four possible timing relationships can be selected by software through the CPOL and CPHA bits in the SPI\_CR1 register.

The CPOL (clock polarity) bit controls the state of the clock level when no data is transmitted. This bit affects both master and slave modes. If CPOL is reset, the SCK pin is low in the idle state. If CPOL is set to 1, the SCK pin is high in the idle state.

If CPHA (clock phase) position 1, the second edge on the SCK pin (falling edge if CPOL bit is reset, rising edge if CPOL position 1) samples the MSBit. That is, the data is latched at the second clock edge.

If the CPHA bit is reset, the first edge on the SCK pin (falling edge if CPOL position 1, rising edge if CPOL bit is reset) samples the MSBit. That is, the data is latched at the first clock edge.

The combination of CPOL and CPHA selects the data sampling clock edge.

Prior to changing the CPOL/CPHA bits the SPI must be disabled by resetting the SPE bit.

The IDLE state of the SCK must correspond to the polarity selected by the SPI\_CR1 register.

Figure 35-8 Data clock timing diagram

The order of the data bits depends on the setting of LSBFIRST (SPI\_CR1 register).

### 35.2.5.2 Data frame format

The SPI shift register may be set to MSB-FIRST or LSB-FIRST by LSBFIRST (SPI\_CR1 register). By using the DFF (SPI\_CR1 register), the number of bits of the data frame is selected, which can be selected to be 8 bits or 16 bits in length. This setting is applicable to both transmission and reception.

### 35.2.6 Configuration of SPI

The configuration procedure is almost the same for master and slave. When a standard communication is to be initialized, perform these steps:

1. Write GPIO registers: Configure MOSI, MISO, and SCK pins
2. Write to the SPI\_CR1 register:
  - 1) Configuring clock baud rate via BR [2: 0]
  - 2) Configure the CPOL and CPHA bits
  - 3) Select simplex or half-duplex mode by configuring RXONLY or BIDIMODE and BIDIOE
  - 4) Configure the LSBFIRST bit
  - 5) Configure SSM and SSI
  - 6) Configure MSTR (in multi-host NSS configuration, to avoid NSS conflicts, the host configures MSTR to prevent MODF errors)
3. Write to SPI\_CR2 register:

- 1) Configure the DS bit to select the data length for the transfer
- 2) Configure SSOE (not required for slave mode)

### 35.2.7 Procedure for enabling SPI

The SPI slave is enabled before the master sends the clock. If not, undesired data transmission might occur. Before starting communication with the master, the data register of the slave must write the data to be sent. The SCK signal must be settled at an idle state level corresponding to the selected polarity before the SPI slave is enabled.

In full duplex mode (or send only), when SPI is enabled and TXFIFO is not empty, or the next write is made to TXFIFO, the host starts communication.

In any host receive-only mode (RXONLY = 1, or BIDIMODE = 1 and BIDIOE = 0), after SPI is enabled, the host starts communicating and immediately provides the clock.

### 35.2.8 Data transmission and reception procedures

#### 35.2.8.1 RXFIFO and TXFIFO

SPI All data communication is through FIFO, with a depth of 4 and a width of 16 bits (when the data frame is set to 8 bits, the width is 8 bits). This enables the SPI to work in a continuous flow, and prevents overruns when the data frame size is short. Each direction has its own FIFO called TXFIFO and RXFIFO. These FIFOs are used in all SPI modes.

The handling of FIFOs depends on the data exchange mode (duplex, simplex) and data frame format. A read access to the SPI\_SR register returns the oldest value stored in RXFIFO that has not been read yet. A write access to the SPI\_DR stores the written data in the TXFIFO at the end of a send queue. The read access must be always aligned with the RXFIFO threshold. The FTLVL and FRLVL bits show the current occupancy of the two FIFOs.

A read access to the SPI\_DR register must be managed by the RXNE event. This event is triggered when data is stored in RXFIFO and the threshold is reached. When RXNE is cleared, RXFIFO is considered to be empty.

Write the data frame to be sent, managed by TXE events. This event is triggered when the TXFIFO level is less than or equal to half of its capacity. Otherwise, TXE is cleared and the TXFIFO is considered as full.

In this way, RXFIFO can store up to two data frames.

Both TXE and RXNE events can be polled or handled by interrupts.

If the next data is received when the RXFIFO is full, an overrun event occurs. An overrun event can be polled or handled by an interrupt.

The set BSY bit indicates that communication is in progress for the current data frame. When the clock signal runs continuously, the BSY flag stays set between data frames at master. However, BSY will keep a minimum of 1 SPI clock low level between each data frame transmission on the slave side.

#### 35.2.8.2 Sequence handling

A few data frames can be passed at single sequence to complete a message. When transmission is enabled, a sequence begins and continues while any data is present in the TXFIFO of the master. The clock signal is continuously supplied by the host until TXFIFO becomes empty, and then stops waiting for additional data.

In receive-only modes, half-duplex (BIDIMODE=1, BIDIOE=0) or simplex (BIDIMODE=0, RXONLY=1) the master starts the sequence immediately when both SPI is enabled and receive-only mode is activated. The clock signal is provided by the master, and it does not stop until either SPI or receive-only mode is disabled by the master. The master receives data frames continuously up to this moment. When the master communicates in continuous mode (the SCK signal is continuous), the master must consider the ability of the slave to process the data stream. When necessary, the host must slow down the communication speed and provide a slower clock, or send separate frames. It should be noted that there is no underflow error signal for the master or slave, and the data from the slave is processed by the master (even if the slave cannot send the correct data in time).

Each sequence must be managed by the NSS pin, and at the same time, one of the slaves to communicate in the multi-slave system is selected. In a single slave system, it is not necessary to use NSS to control the slave, but it is usually preferable to provide NSS to synchronize the beginning of each data sequence of communication. NSS can be managed by both software and hardware.

When the BSY bit is set it signifies an ongoing data frame transaction. When the dedicated frame transaction is finished, the RXNE flag is raised. The last bit is sampled and the entire data frame is stored in the RXFIFO.

### 35.2.8.3 Procedure for disabling the SPI

In full duplex or single transmission mode, the host can complete the interaction after providing the data to be sent. In this case, after the last data interaction, the clock is stopped. In these modes, the user must use the standard shutdown process before the SPI can shut down. SPI is prohibited when the host sends. If one frame interaction is in progress at this time, or the next data frame exists in TXFIFO, the function of SPI cannot be guaranteed.

When the host is in any receive-only mode, the only way to stop the continuous clock is to turn off SPI (SPE = 0).

Data received but not read remains stored in RXFIFO when the SPI is disabled, and must be processed the next time the SPI is enabled, before starting a new sequence. To prevent having unread data, ensure that RXFIFO is empty when disabling the SPI.

Standard disable procedure is based on pulling BSY status together with FTLVL to check if a transmission session is fully completed. The communication being interacted can also be authenticated by specific checks, such as:

- When NSS signal is managed by software and master has to provide proper end of NSS pulse for slave.
- When transactions' streams from FIFO are completed while the last data frame is still ongoing in the peripheral bus.

The correct disable procedure is (except when receive only mode is used):

1. Wait for FTLVL = 0 (no data to send)
2. Wait until BSY=0 (the last data frame is processed)
3. Disable the SPI (SPE=0).
4. Read data until FRLVL = 0 (read all the received data)

The correct disable procedure for certain receive only modes is:

1. Interrupt the receive flow by disabling SPI (SPE=0) in the specific time window while the last data frame is ongoing.
2. Wait until BSY=0 (the last data frame is processed).
3. Read data until FRLVL = 0 (read all the received data)

#### 35.2.8.4 Data packing

When the data frame size fits into 8 bits, data packing is used automatically when any read or write 16-bit access is performed on the SPI\_DR register. The double data frame pattern is handled in parallel in this case.

The figure below provides an example of data packing mode sequence handling. After a single 16-bit access by the sender, two data frames are sent. On the receiver side, if the RXFIFO width is 16 bits, an RXNE event is immediately generated. The receiver then has to access both data frames by a single 16-bit read of SPI\_DR as a response to this single RXNE event. The Rx FIFO threshold setting and the following read access must be always kept aligned at the receiver side, as data can be lost if it is not in line.

At the sending end, an odd sequence can be written using 8-bit access mode to complete communication; At the receiving end, in order to generate an RXNE event, the receiver must change the Rx\_FIFO threshold when the last data frame is received.

Figure 35-9 Packing data in FIFO for transmission and reception

#### 35.2.8.5 Communication timing

Some typical timing schemes are explained in this section. These schemes are valid no matter if the SPI events are handled by polling, interrupts. For simplicity, the LSBFIRST=0, CPOL=0 and CPHA=1 setting is used as a common assumption here.

1. When NSS is valid, SPI is enabled, and the slave starts controlling MISO. When NSS is released or SPI is turned off; The slave loses control of the MISO. Sufficient time must be provided for the slave to prepare data dedicated to the master in advance before its transaction starts. At the master, the SPI peripheral takes control at MOSI and SCK signals (occasionally at NSS signal as well) only if SPI is enabled. If the SPI is turned off, the SPI peripherals are disconnected from the GPIO, and the level values on these lines depend on the GPIO setting.
2. At the master, BSY stays active between frames if the communication is continuous. At the slave, BSY signal always goes down for at least one clock cycle between data frames.
3. The TXE signal is cleared only if TXFIFO is full.

4. The TXE interrupt is generated just after the TXEIE is set. When the TXE signal is active, start writing data to the TXFIFO until the TXFIFO becomes full.

Figure 35-10 host full-duplex communication diagram (bit frame = 8)

### 35.2.9 SPI status flags

Three status flags are provided for the application to completely monitor the state of the SPIbus.

#### 35.2.9.1 Tx FIFO empty flag (TXE)

The TXE flag is set when transmission TXFIFO has enough space to store data to send. TXE flag is linked to the TXFIFO level. The flag goes high and stays high until the TXFIFO level is lower or equal to 1/2 of the FIFO depth. An interrupt can be generated if the TXEIE bit in the SPI\_CR2 register is set.

#### 35.2.9.2 Rx buffer not empty (RXNE)

The RXNE flag is set depending on the FRXTH bit value in the SPI\_CR2 register.

#### 35.2.9.3 Busy flag (BSY)

The BSY flag is set and cleared by the hardware (writing this bit has no effect). This flag indicates the SPI communication status.

When it is set to '1' by hardware, it indicates that the SPI is in communication.

Before the software wants to shut down the SPI module, the BSY flag can be used to detect whether the transmission is finished, which can avoid corrupting the last transmission.

The BSY flag is cleared under any one of the following conditions:

- When the SPI is correctly disabled
- Host mode, when the MODF flag is generated
- Host mode, when the transmission is complete, there is no more data to send
- In Slave mode, when the BSY flag is set to '0' for at least one SPI clock cycle between each data transfer.

Note: Do not use the BSY flag for each data transmission and reception. It is better to use the TXE and RXNE flags instead.

### 35.2.10 Error flags

#### 35.2.10.1 Mode fault (MODF)

Master mode failure (MODF) only occurs when: when NSS is used as the input signal (SSOE = 0), the NSS pin of the master device is pulled low under hardware mode management; Or when the SSI bit is set to '0' under software mode management of the NSS pin. This automatically sets the MODF bit. Master mode fault affects the SPI interface in the following ways:

- The MODF bit is set and an SPI interrupt is generated if the ERRIE bit is set.
- The SPE bit is cleared. This blocks all output from the device and disables the SPI interface.
- The MSTR bit is cleared, thus forcing the device into slave mode.

Use the following software sequence to clear the MODF bit:

1. Make a read or write access to the SPI\_SR register while the MODF bit is set.
2. Then write to the SPI\_CR1 register.

To avoid any multiple slave conflicts in a system comprising several MCUs, the NSS pin must be pulled high during the MODF bit clearing sequence. The SPE and MSTR bits can be restored to their original state after this clearing sequence.

As a security, hardware does not allow the SPE and MSTR bits to be set while the MODF bit is set. In the slave device, the MODF position 1 cannot be placed. However, in a multi-master mode configuration, the device may be in a slave mode when at MODF position 1. In this case, the MODF bit indicates that the system control may have a multi-master mode conflict. You can use the interrupt procedure to fully recover from this state by performing a reset or returning to the default state.

#### 35.2.10.2 Overflow Error (OVR)

An overflow error occurs when data is received by a master or a slave, and the RXFIFO does not have enough space to store the received data. This error occurs if the software does not have enough time to read away the previously received data (stored in the RXFIFO).

When an overflow error occurs, the newly received data will not overwrite the data previously stored in RXFIFO. The newly received value is discarded, and all data transmitted subsequently is lost.

Clearing the OVR bit is done by a read access to the SPI\_DR register followed by a read access to the SPI\_SR register.

#### 35.2.11 SPI interrupts

Table 35-1 SPI interrupt requests

| Interrupt event         | Event flag | Enable control bit |
|-------------------------|------------|--------------------|
| TXFIFO empty            | TXE        | TXEIE              |
| RXFIFO non-empty        | RXNE       | RXNEIE             |
| Master Mode fault event | MODF       | ERRIE              |
| Overrun error           | OVR        | ERRIE              |

#### 35.2.12 CRC Calculation

Two separate CRC calculators are implemented in order to check the reliability of transmitted and received data. SPI provides CRC8 or CRC16 calculations independent of frame data length and can be fixed to 8 or 16 bits. For all other data frame lengths, no CRC is available.

**35.2.12.1 CRC standard**

Before SPI is enabled ( $SPE = 1$ ), CRC calculation is enabled by setting the CRCEN bit in the SPI\_CR1 register. The calculation is processed at the sample clock edge defined by the CPHA and CPOL bits in the SPI\_CR1 register. The calculated CRC value is automatically checked at the end of the data block, and the transmission is managed by the CPU or DMA. When the CRC calculated internally of the received data does not match the received CRC, the CRCERR flag is set to indicate a data error. The correct procedure to handle the CRC calculation depends on the SPI configuration and the transfer management mode selected.

**35.2.12.2 CRC transfer managed by CPU**

The CRCNEXT bit must be set before the end of transmission of the last data frame is received, and is used to indicate that the transmission of the CRC frame begins after the currently processed data frame. CRC calculation is frozen during CRC transaction.

The received CRC is stored in the RXFIFO like a data byte or word. In CRC mode, the receive buffer must be treated as a single 16-bit buffer for receiving only one data frame at a time. The CRC format transmission typically requires an extra data frame at the end of the data transmission. When setting up an 8-bit data frame that passes a 16-bit CRC check, two more frames are needed to send the full CRC value.

When the last CRC data is received, an automatic check is performed, comparing the received value with the SPI\_RXCRC register. The software must check the CRCERR flag in the SPI\_SR register to determine the data transfer status. The software clears the CRCERR flag by writing a "0" to it. After CRC is received, the CRC value is stored in the RXFIFO and the SPI\_DR register must be read to clear the RXNE flag

**35.2.12.3 CRC transmission under DMA**

When SPI communication is enabled using DMA mode with CRC, the transmission and reception of CRC at the end of communication is done automatically (except for reading CRC data in receive-only mode) and the CRCNEXT bit does not have to be processed by software. The counter of the SPI transmission DMA channel must be set to the number of data frames to be transmitted, which does not include CRC frames. At the receiving end, the received CRC value is automatically processed by the DMA at the end of the transmission, but the user must take care to clear the received CRC information from the RXFIFO, as it is always deposited in the RXFIFO. In the full-duplex mode, the counter of the received DMA channel may be set to the number of data frames including CRC to be received.

In receive only mode, the DMA receive channel counter should contain only the amount of data transmitted, not the CRC frame. At the end of the data and CRC transfer, if an error occurs during the transfer, the CRCERR flag in the SPI\_SR register is set.

**35.2.13 TI mode**

The SPI interface is compatible with TI protocol. The SPI can be configured using the FRF bit of the SPI\_CR2 register to be compatible with this protocol.

Both the clock polarity and phase are forced to follow the TI protocol regardless of the settings in SPI\_CR1. NSS management is also specific to the TI protocol, in which case NSS management cannot be configured through the SPI\_CR1 and SPI\_CR2 registers (SSM, SSI, and SSOE).

In slave mode, the SPI baud rate prescaler is used to control the moment when the MISO pin is switched to the high impedance state when the current transmission is complete. Any baud rate can be used, making it possible to determine this moment with optimal flexibility. The baud rate is usually set to the external master clock baud rate. The release for the MISO signal to become a high impedance state depends on the internal resynchronization and the baud rate value set by the BR [2: 0] bit of the SPI\_CR1 register. It is given by the formula:

$$\frac{t_{baud\_rate}}{2} + 4 \times t_{pclk} < t_{release} < \frac{t_{baud\_rate}}{2} + 6 \times t_{pclk}$$

If the slave device detects a misaligned NSS pulse during data frame transmission, the TIFRE flag will be set to 1.

## 35.3 I2S functional description

### 35.3.1 Introduction

The I2S interface uses roughly the same pins, flags, and interrupts as the SPI interface.

The I2S shares three common pins with the SPI:

SD: serial data (mapped to MOSI pin), used to send and receive data of two time division multiplexed channels;

WS: word selection (mapped to NSS pin), output as data control signal in master mode and input in slave mode;

CK: Serial clock (mapped to SCK pin), output as clock signal in master mode and input in slave mode.

An additional pin can be used when a master clock output is needed for some external audio devices:

MCK: Master clock (independent mapping), used as an extra clock signal pin for outputting when I2S is configured in master mode and the MCKOE bit of register SPI\_I2SPR is '1'. The frequency of the output clock signal is preset to  $256 \times F_s$ , where  $F_s$  is the sampling frequency of the audio signal.

The I2S uses its own clock generator to produce the communication clock when it is set in master mode. This clock generator is also the source of the master clock output. There are two additional registers in I2S mode, one is the register SPI\_I2SPR related to the clock generator configuration, and the other is the I2S general configuration register SPI\_I2SCFGR (which can set parameters such as audio standard, slave/master mode, data format, packet frame, clock polarity, etc.).

The I2S function can be enabled by setting the I2SMOD bit of the register SPI\_I2SCFGR to '1'. At this time, the SPI module may be used as an I2S audio interface.

The SPI\_CR1 register and all CRC registers are not used in the I2S mode. Likewise, the SSOE bit in the SPI\_CR2 register and the MODF and CRCERR bits in the SPI\_SR are not used.

I2S uses the same register SPI\_DR as SPI for 16-bit mode data transfer.

### 35.3.2 Supported audio protocols

The three-wire bus supports time division multiplexing of audio data on two channels: the left channel and the right channel, but only one 16-bit register is used for transmission or reception. Therefore, when writing data to the data register, the software must write the corresponding data according to the channel currently in transmission; Similarly, when the register data is read, it is determined to which channel the

received data belongs by checking the CHSIDE bit of the register SPI\_SR. The left channel always sends data before the right channel (the CHSIDE bit is meaningless under the PCM protocol).

There are four combinations of data and frame formats, and data can be sent in the following formats:

- 16-bit data packed in a 16-bit frame
- 16-bit data packed in a 32-bit frame
- 24-bit data packed in a 32-bit frame
- 32-bit data packed in a 32-bit frame

When extending to a 32-bit frame using 16-bit data, the first 16 bits (MSB) are meaningful data and the last 16 bits (LSB) are forced to 0, which requires no software intervention and no DMA request (only one read/write operation is required). The 24-bit and 32-bit data frames need two CPU read or write operations to/from the SPI\_DR register or two DMA operations if the DMA is preferred for the application. For 24-bit data frame specifically, the 8 non-significant bits are extended to 32 bits with 0-bits (by hardware). For all data formats and communication standards, the highest bit (MSB) is always sent first.

The I2S interface supports four audio standards, configurable using the I2SSTD [1:0] and PCMSYNC bits in the SPI\_I2SCFGR register.

### 35.3.2.1 I2S Philips standard

For this standard, the WS signal is used to indicate which channel is being transmitted. This pin is active 1 clock cycle before the first bit of data (MSB) is sent.

Figure 35-11 I2S Philips protocol waveform (16/32 bit full accuracy, CKPOL = 0)

When CKPOL = 0, the transmitter changes data on the falling edge of the clock signal (CK) and the receiver reads data on the rising edge. The WS signal is also latched on the falling edge of clock signal. When CKPOL = 1, the transmitter also changes data at the falling edge of the clock signal (CK).

Figure 35-12 I2S Philips protocol standard waveform (24-bit frame, CKPOL = 0)

This mode needs two write or read operations to/from the SPI\_DR register.

Figure 35-13 I2S Philips protocol standard waveform (16-bit extension to 32-bit packet frame, CKPOL = 0)

When CKPOL = 1, the transmitter also changes data at the falling edge of the clock signal (CK)

Figure 35-14 I2S Philips protocol standard waveform (16-bit extension to 32-bit packet frame, CKPOL = 1)

When 16-bit data frame extended to 32-bit channel frame is selected during the I2S configuration phase, only one access to the SPI\_DR register is required. The 16 remaining bits are forced by hardware to 0x0000 to extend the data to 32-bit format.

If the data to be transmitted or received is 0x76A3 (extended to 32 bits is 0x76A30000), the required operation is shown in the figure below.

只需要操作一次 SPI\_DR

Figure 35-15 I2S Data Reception

The MSB needs to be written to the register SPI\_DR when transmitting; A flag bit TXE of '1' indicates that new data can be written, and an interrupt can be generated if a corresponding interrupt is allowed. This takes place even if 0x0000 have not yet been sent because it is done by hardware. On receipt, the flag bit RXNE is set to '1' after receiving a 16-bit half-word higher (MSB), and if the corresponding interrupt is allowed, an interrupt can be generated.

In this way, more time is provided between two write or read operations to prevent underrun or overrun conditions.

### 35.3.2.2 MSB justified standard

Under this standard, the WS signal and the first data bit, the highest bit (MSB), are generated simultaneously.

Figure 35-16 MSB Alignment 16-bit or 32-bit Full Precision, CPKOL = 0

When CKPOL = 1, the transmitter also changes data at the falling edge of the clock signal (CK)

Figure 35-17 MSB Alignment 16-bit or 32-bit Full Precision, CPKOL = 1

Data are latched on the falling edge of CK (for transmitter) and are read on the rising edge (for the receiver).

Figure 35-18 MSB aligned 24-bit data, CPKOL = 0

Figure 35-19 MSB aligned 16-bit data extension to 32-bit packet frame, CPKOL = 0

When CKPOL = 1, the transmitter also changes data at the falling edge of the clock signal (CK). The next TXE event occurs as soon as valid data begins to be sent from the SD pin. Upon reception, an RXNE event occurs once valid data is received (instead of the 0x0000 portion).

### 35.3.2.3 LSB justified standard

This standard is similar to the MSB alignment standard (no difference in 16-bit or 32-bit full-precision frame formats). When CKPOL = 1, the transmitter also changes data at the falling edge of the clock signal (CK)

Figure 35-20 LSB alignment 16-bit or 32-bit full accuracy, CKPOL = 0

- In send mode

If data 0x3478AE have to be transmitted, two write operations to the SPI\_DR register are required by software or by DMA. The operation flow is shown below.

Figure 35-21 Requires Operation to Read 0x3478AE

- In receive mode

If you want to receive data 0x3478AE, you need to read the register SPI\_DR once when two consecutive RXNE events occur.

Figure 35-22 requires operation to receive 0x3478AE

Figure 35-23 LSB aligned 16-bit data extension to 32-bit packet frame, CPOL = 0

When CKPOL = 1, the sender also changes data at the falling edge of the clock signal (CK). When 16-bit data frame extended to 32-bit channel frame is selected during the I2S configuration phase, only one access to the SPI\_DR register is required. At this time, the upper half word (16-bit MSB) extended to 32 bits is set to 0x0000 by hardware.

If the data to be transmitted or received is 0x76A3 (extended to 32 bits is 0x0000 76A3), the required operation: SPI\_DR only needs to be operated once.

At the time of transmission, if the TXE is '1', the user needs to write the data to be transmitted (i.e., 0x76A3). The 0x0000 used to expand to 32 bits is partially sent out by the hardware first. Once valid data starts to be sent out from the SD pin, the next TXE event occurs. Upon reception, an RXNE event occurs once valid data is received (instead of the 0x0000 portion). In this way, more time is provided between two write or read operations to prevent underrun or overrun conditions.

#### 35.3.2.4 PCM standard

For the PCM standard, there is no need to use channel-side information. The two PCM modes (short and long frame) are available and configurable using the PCMSYNC bit in SPI\_I2SCFGR register.

Figure 35-24 PCM standard waveform (16 bits)

When CKPOL = 1, the transmitter also changes data at the rising edge of the clock signal (CK). For long frames, in main mode, the valid time of the WS signal used for synchronization is fixed to 13 bits. For short frames, the length of the WS signal used for synchronization is only 1 bit.

When CKPOL = 1, the transmitter also changes data at the rising edge of the clock signal (CK)

Regardless of which mode (master or slave), which synchronization mode (short frame or long frame), the time difference between two consecutive frames of data and between two synchronization signals

(even in the slave mode) needs to be determined by setting the DATLEN bit and the CHLEN bit of the SPI\_I2 SCFGR register.

### 35.3.3 Clocks

The I2S bit rate determines the data flow on the I2S data line and the I2S clock signal frequency. I.e  
 $\text{I2S bit rate} = \text{number of bits per channel} \times \text{number of channels} \times \text{audio sampling frequency}$

For a 16-bit audio, left and right channel, the I2S bit rate is calculated as follows:

$\text{I2S bitrate} = 16 \times 2 \times f_s$ ;

If the packet length is 32 bits, there is:

$\text{I2S bitrate} = 32 \times 2 \times f_s$

Figure 35-25 Audio Sampling Definition

When the master mode is configured, a specific action needs to be taken to properly program the linear divider in order to communicate with the desired audio frequency. The sampling frequency of the audio may be 96 kHz, 48 kHz, 44.1 kHz, 32 kHz, 22.05 kHz, 16 kHz, 11.025 kHz, or 8 kHz (or any value within this range). In order to obtain the required frequency, it is obtained by setting the linear frequency divider according to the following formula, when the master clock needs to be generated (the MCKOE bit of the register SPI\_I2SPR is '1'):

When the frame length of the channel is 16 bits,  $F_s = \text{I2SxCLK} / [(16 \times 2) \times ((2 \times \text{I2SDIV}) + \text{ODD}) \times 8]$

When the frame length of the channel is 32 bits,  $F_s = \text{I2SxCLK} / [(32 \times 2) \times ((2 \times \text{I2SDIV}) + \text{ODD}) \times 4]$

When the master clock is turned off (MCKOE bit is '0'):

When the frame length of the channel is 16 bits,  $F_s = \text{I2SxCLK} / [(16 \times 2) \times ((2 \times \text{I2SDIV}) + \text{ODD})]$

When the frame length of the channel is 32 bits,  $F_s = \text{I2SxCLK} / [(32 \times 2) \times ((2 \times \text{I2SDIV}) + \text{ODD})]$

Use the standard 8MHz HSE clock to get the accurate audio frequency, see EXCEL table.

### 35.3.4 Sending and receiving

#### 35.3.4.1 Master mode

The I2S can be configured in master mode. This means that the serial clock is generated on the CK pin as well as the Word Select signal WS. Outputting or not outputting the master clock (MCK) can be selected by setting the MCKOE bit of the register SPI\_I2SPR.

##### 1) Sending process

When one and a half word (16 bits) of data is written to the transmission buffer, the transmission flow begins.

Lets assume the first data written into the Tx buffer corresponds to the left channel data. When data are transferred from the Tx buffer to the shift register, TXE is set and data corresponding to the right channel have to be written into the Tx buffer. The CHSIDE flag indicates which channel is to be transmitted. It

has a meaning when the TXE flag is set because the CHSIDE flag is updated when TXE goes high. A full frame has to be considered as a left channel data transmission followed by a right channel data transmission. It is not possible to have a partial frame where only the left channel is sent.

The data half-word is parallel loaded into the 16-bit shift register during the first bit transmission, and then shifted out, serially, to the MOSI/SD pin, MSB first. The TXE flag is set after each transfer from the Tx buffer to the shift register and an interrupt is generated if the TXEIE bit in the SPI\_CR2 register is set.

The operation of writing data depends on the chosen I2S standard, as detailed in Section 5.2. To ensure a continuous audio data transmission, it is mandatory to write the SPI\_DR register with the next data to transmit before the end of the current transmission. To switch off the I2S, by clearing I2SE, it is mandatory to wait for TXE = 1 and BSY = 0.

## 2) Receiving Process

Whatever the data or channel length, the audio data are received by 16-bit packets. This means that each time the Rx buffer is full, the RXNE flag is set and an interrupt is generated if the RXNEIE bit is set in SPI\_CR2 register. Depending on the data and channel length configuration, the audio value received for a right or left channel may result from one or two receptions into the Rx buffer. Clearing the RXNE bit is performed by reading the SPIx\_DR register. CHSIDE is updated after each reception. It is sensitive to the WS signal generated by the I2S cell. The operation of reading the data depends on the selected I2S standard.

If data are received while the previously received data have not been read yet, an overrun is generated and the OVR flag is set. If the ERRIE bit is set in the SPI\_CR2 register, an interrupt is generated to indicate the error.

To switch off the I2S, specific actions are required to ensure that the I2S completes the transfer cycle properly without initiating a new data transfer.

Note: The BSY flag is kept low during transfers.

### 35.3.4.2 Slave mode

For the slave configuration, the I2S can be configured in transmission or reception mode. The operating mode is following mainly the same rules as described for the I2S master configuration. In slave mode, there is no clock to be generated by the I2S interface. The clock and WS signals are input from the external master connected to the I2S interface. There is then no need, for the user, to configure the clock.

## 1) Sending process

The transmission sequence begins when the external master device sends the clock and when the NSS\_WS signal requests the transfer of data. The slave has to be enabled before the external master starts the communication. The I2S data register has to be loaded before the master initiates the communication.

For the I2S, MSB justified and LSB justified modes, the first data item to be written into the data register corresponds to the data for the left channel. When the communication starts, the data are transferred from the Tx buffer to the shift register. The TXE flag is then set in order to request the right channel data to be written into the I2S data register.

The CHSIDE flag indicates which channel is to be transmitted. Compared to the master transmission mode, in slave mode, CHSIDE is sensitive to the WS signal coming from the external master. This means that the slave needs to be ready to transmit the first data before the clock is generated by the master. WS assertion corresponds to left channel transmitted first.

Note: The I2SE has to be written at least two PCLK cycles before the first clock of the master comes on the CK line.

The data half-word is parallel-loaded into the 16-bit shift register (from the internal bus) during the first bit transmission, and then shifted out serially to the MOSI/SD pin MSB first. The TXE flag is set after each transfer from the Tx buffer to the shift register and an interrupt is generated if the TXEIE bit in the SPI\_CR2 register is set. Note that the TXE flag should be checked to be at 1 before attempting to write the Tx buffer.

To ensure a continuous audio data transmission, it is mandatory to write the SPI\_DR register with the next data to transmit before the end of the current transmission. An underrun flag is set and an interrupt may be generated if the data are not written into the SPI\_DR register before the first clock edge of the next data communication. This indicates to the software that the transferred data are wrong. If the ERRIE bit is set into the SPI\_CR2 register, an interrupt is generated when the UDR flag in the SPI\_SR register goes high. In this case, it is mandatory to switch off the I2S and to restart a data transfer starting from the left channel.

To switch off the I2S, by clearing the I2SE bit, it is mandatory to wait for TXE = 1 and BSY = 0.

## 2) Receiving Process

Whatever the data length or the channel length, the audio data are received by 16-bit packets. This means that each time the RX buffer is full, the RXNE flag in the SPI\_SR register is set and an interrupt is generated if the RXNEIE bit is set in the SPI\_CR2 register. Depending on the data length and channel length configuration, the audio value received for a right or left channel may result from one or two receptions into the RX buffer. The CHSIDE is updated each time data is received (to be read out from the SPI\_DR), which corresponds to the WS signal generated by the I2S unit. Clearing the RXNE bit is performed by reading the SPI\_DR register.

When the previously received data is not read out and new data is received, overflow is generated, and the flag bit OVR is set to '1'; If the ERRIE bit of the register SPI\_CR2 is '1', an interrupt is generated indicating that an error has occurred.

To turn off the I2S function, the I2SE bit needs to be cleared '0' when the last RXNE = 1 is received.

Note: The external master I2S device needs to have the ability to send/receive 16-bit or 32-bit packets over the audio channel.

### 35.3.5 Flag bit

#### 35.3.5.1 Status flag

Three status flags are provided for the application to fully monitor the state of the I2S bus.

##### 1) Busy flag bit (BSY)

The BSY flag is set and cleared by the hardware (writing this bit has no effect), and this flag bit indicates the status of the I2S communication layer. When this bit is '1', it indicates that I2S communication is in progress, with one exception: in primary reception mode (I2SCFG = 11), the BSY flag is always low

during reception. The BSY flag can be used in certain modes to detect the end of a transfer so that the software can disable the SPI which does not provide a clock for the peripheral. This avoids corrupting the last transfer. The BSY flag is set when a transfer starts, except when the I2S is in master receiver mode.

The BSY flag is cleared:

- When the transmission ends (except for the main transmit mode, where communication is continuous);
- When the I2S module is turned off.

When communication is continuous:

- In the main transmit mode, the BSY flag is always high throughout the transmission;
- In slave mode, the BSY flag goes low for 1 I2S clock cycle between each data item transmission.

#### 2) Send buffer null flag bit (TXE)

When set, this flag indicates that the Tx buffer is empty and the next data to be transmitted can then be loaded into it. The TXE flag is reset when the Tx buffer already contains data to be transmitted. When I2S is turned off (I2SE bit is '0'), the flag bit is also '0'.

#### 3) Receive buffer non-empty flag bit (RXNE)

When set, this flag indicates that there are valid received data in the RX Buffer. It is reset when SPI\_DR register is read.

#### 4) Channel Flag (CHSIDE)

In transmission mode, this flag is refreshed when TXE goes high. It indicates the channel side to which the data to transfer on SD has to belong. In case of an underrun error event in slave transmission mode, this flag is not reliable and I2S needs to be switched off and switched on before resuming the communication. In reception mode, this flag is refreshed when data are received into SPI\_DR. It indicates from which channel side data have been received. If an error occurs (e.g., overflow OVR), this flag bit is meaningless and I2S needs to be turned off and turned on again (and the configuration of I2S should be modified if necessary).

This flag has no meaning in the PCM standard (for both Short and Long frame modes).

When the OVR or UDR flag in the SPI\_SR is set and the ERRIE bit in SPI\_CR2 is also set, an interrupt is generated. This interrupt can be cleared by reading the SPI\_SR status register.

### 35.3.5.2 Error flags

There are two error flags for the I2S cell.

#### 1) Underflow flag bit (UDR)

In slave transmission mode, this flag is set when the first clock for data transmission appears while the software has not yet loaded any value into SPI\_DR. It is available when the I2SMOD bit in the SPI\_I2SCFGR register is set. An interrupt may be generated if the ERRIE bit in the SPI\_CR2 register is set. The UDR bit is cleared by a read operation on the SPI\_SR register.

#### 2) Overflow flag bit (OVR)

This flag is set when data are received and the previous data have not yet been read from the SPI\_DR register. As a result, the incoming data are lost. An interrupt may be generated if the ERRIE bit is set in the SPI\_CR2 register. At this time, the contents of the received cache are not refreshed to new data sent from the transmitting device. A read operation to register SPI\_DR returns the last correctly received

data. All other 16-bit data sent by the sending device after the overflow occurs will be lost. The flag bit is cleared by first reading register SPI\_SR and then reading register SPI\_DR.

### 35.3.6 DMA functionality

Except for CRC function, same as SPI. Because there is no data transfer protection function in I2S mode.

### 35.3.7 Interrupts and events

Table 35-2 I2S interrupt requests

| Interrupt event               | Event flag | Enable control bit |
|-------------------------------|------------|--------------------|
| Transmit buffer empty flag    | TXE        | TXEIE              |
| Receive buffer not empty flag | RXNE       | RXNEIE             |
| Underrun error                | OVR        | ERRIE              |
| Overrun error                 | UDR        |                    |

|-------|---------------|-----|-------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| 15: 0 | RxCRC [15: 0] | R   | 0           | When CRC calculation is enabled in the Receive CRC register, RxCRC [15: 0] contains the CRC value calculated from the received bytes. This register is reset when the CRCEN bit in SPI_CR1 register is written to 1. The CRC is calculated serially using the polynomial programmed in the SPI_CRCPR register. Only the 8 LSB bits are considered when the CRC frame format is set to be 8-bit length. CRC calculation is done based on any CRC8 standard. The entire 16-bits of this register are considered when a 16-bit CRC frame format is selected. CRC calculation is done based on any CRC16 standard. Note: A read to this register when the BSY Flag is set could return an incorrect value. Note: These bits are not used in I2S mode. |

## 36. Inter-integrated circuit (I2C) interface

### 36.1 Introduction

The I2C (Inter-integrated circuit) bus interface handles communications between the microcontroller and the serial I2C bus. It provides multimaster capability, and controls all I2C bus-specific sequencing, protocol, arbitration and timing. It supports Standard-mode (Sm), Fast-mode (Fm) and Fast-mode plus (Fm+). Depending on the needs of a specific device, DMA can be used to reduce the burden on the CPU.

### 36.2 Main Features

- Slave and master modes
- Multi-master function: can be used as a master or a slave
- As Master
  - Generate clock
  - Generate start and stop signals
- As Slave
  - Programmable I2C address detection
  - Dual address capability that can respond to 2 slave addresses (with 1 configurable mask)
  - Detect stop bit
- Supports 7/10-bit addressing mode
- Support broadcast call function
- Supports different communication speeds
  - Standard (up to 100 KHz)
  - Fast (up to 400 KHz)
  - Fast enhancement (up to 1 MHz)
- Status flag bit:
  - Send/receive mode flag
  - Byte transfer completion flag
  - I2C Bus busy flag
- I2S error flag
  - Host Mode Arbitration Lost
  - Answer (ACK) after address/data transfer failed
  - Error start/stop condition
  - Disable overflow or underflow when stretching the clock function
- 2 interrupt vectors
  - 1 event interrupt for address/data communication success
  - 1 error interrupt
- Optional length clock function
- Support DMA function
- Generation or verification of configurable PEC (Packet Error Detection):
  - The PEC value can be transmitted as the last byte in the transmit mode

- PEC error check for last received byte
- SMBus 2.0 support
  - 25 ms Clock low timeout delay
  - 10 ms master accumulated clock low extension time
  - 25 ms slave accumulated clock low extension time
  - Hardware PEC generation/verification with ACK control
  - Supports Address Resolution Protocol (ARP)
  - Timeout and idle condition detection
- Support SMBus
- Supports wake-up from Stop mode when addresses match
  - Supports configurable timeout time during wake-up

Figure 36-1 I2C Module

## 36.3 I2C functional description

### 36.3.1 Introduction

Figure 36-2 I2C bus protocol

The interface can operate in one of the four following modes:

- Slave transmitter
- Slave receiver
- Master transmitter
- Master receiver

By default, the I2C interface operates in Slave mode. The interface automatically switches from the slave mode to the master mode after generating the start condition; When the arbitration is lost or a stop signal is generated, the master mode is switched to the slave mode in the case where the multi-master function is allowed

In Master mode, the I2C interface initiates a data transfer and generates the clock signal. A serial data transfer always begins with a start condition and ends with a stop condition. Both start and stop conditions are generated in master mode by software.

As a slave, the I2C interface can recognize its own address (7-bit or 10-bit) and the broadcast call address. The General Call address detection may be enabled or disabled by software.

Data and addresses are transferred as 8-bit bytes, MSB first. The 1 or 2 bytes following the start condition are addresses (1 byte for 7-bit mode and 2 bytes for 10-bit mode). Addresses are only sent in master mode.

Within the first always clock after a byte is transmitted, the receiver must send back an acknowledgment bit (ACK) to the sender.

### 36.3.2 Clocks

The input clock of the I2C module is the APB clock. The module generates an SCL clock internally and then outputs it to the bus to the slave.

The SCL generation mechanism is as follows: There is a counter that counts the high and low levels according to the value of the CCR register (the CCR register determines the length of the high and low levels). In addition, the CCR register also controls the selection of standard mode, fast mode and fast boost mode, as well as the duty cycle of SCL high and low levels.

### 36.3.3 Packet Error Check (PEC)

The packet error check (PEC) calculator is used to improve the reliability of communication. This calculator uses a programmable polynomial to calculate each bit of data.

- The PEC calculation is enabled by the ENPEC bit of the I2C\_CR1 register. The PEC uses the CRC-8 algorithm to calculate all information bytes, including addresses and read/write bits.
  - On transmission: The PEC bit in the I2C\_CR1 register is set at the last Tx event, and the PEC will be transmitted after this byte.
  - On receive: Set the PEC bit in the I2C\_CR1 register at the last RxNE event, and if the next received byte is not equal to the internally calculated PEC, the receiver will send a NACK. If it is the main receiver, regardless of the result of proofreading, NACK will be sent after PEC. The PEC bit must be set before receiving an ACK pulse for the current byte.
- The PECERR error flag/interrupt is available in the I2C\_SR1 register.
- If both DMA and PEC calculators are activated:
  - At the time of transmission: When the I2C interface receives an EOT (corresponding to the number of bytes transmitted by DMA) signal from the DMA controller, it automatically sends a PEC after the last byte.
  - On reception: When the I2C interface receives an EOT\_1 signal from the DMA, it will automatically take the next byte as the PEC and will check it. A DMA request is generated after the PEC is received.
- To allow intermediate PEC transmissions, there is a control bit (LAST bit) in the I2C\_CR2 register that determines whether it is really the LAST DMA transmission. If it is indeed the DMA request of the last master receiver, the NACK is automatically sent after the last byte is received.
- PEC calculation is invalid when arbitration is lost.

### 36.3.4 Slave mode of I2C

By default, the I2C interface operates in Slave mode. To switch from slave mode to master mode, you need to generate a start condition. The peripheral input clock must be programmed in the I2C\_CR2 register in order to generate correct timings. The peripheral input clock frequency must be at least:

2 MHz in Sm mode

4 MHz in Fm mode

In Fast mode plus: 16MHz

Set slave address and address masking:

As soon as a start condition is detected, the address is received from the SDA line and sent to the shift register. Then it is compared with the address of the interface (OAR1) or the General Call address (if ENGCG = 1). If extra addresses are enabled (ENDUAL = 1), the address is compared to the chip's OAR2 address, and the address in the OAR2 register can be masked by OA2MSK [2: 0], starting at the 7th bit upper of OA2, only OA2 [7: 2], OA2 [7: 3], OA2 [7: 4], OA2 [7: 5], OA2 [7: 6] or OA2 [7] are compared to the received address, respectively, when OA2MSK is configured to 1 through 6. If OA2MSK = 7, all 7-bit addresses received (except reserved addresses) are answered.

**Address mismatch** (header segment or address mismatch): The I2C interface ignores it and waits for another start condition.

**Address matching:** The I2C interface generates the following timing:

- An acknowledged pulse if the ACK bit is set
- The ADDR bit is set by hardware and an interrupt is generated if the ITEVFEN bit is set
- If ENDUAL = 1, the software must read the DUALF bit to confirm which slave address was responded to

In slave mode that TRA bit indicate whether it is currently in receiver mode or transmitter mode

#### 36.3.4.1 Slave send mode

After receiving the address and clearing the ADDR bit, (if the lowest bit of the address byte is 1) Slave sends data (bytes) from the DR register to the SDA via the internal shift register.

Slave pulls the SCL low until the ADDR bit is cleared and the data to be sent has been written to the DR register (refer to EV1, EV3).

When the acknowledge pulse is received: The TxE bit is set by hardware with an interrupt if the ITEVFEN and the ITBUFEN bits are set.

If TxE is set and some data were not written in the I2C\_DR register before the end of the next data transmission, the BTF bit is set. Slave pulls the SCL down until the BTF bit is cleared by the software (after reading I2C\_SR1, writing to the I2C\_DR register).

Figure 36-3 Transfer sequence diagram for slave transmitter

Description: S = Start, SR = Repeated Start, P = Stop, A = Acknowledge, NA = Non-acknowledge, EVx = Event (interrupt when ITEVFEN = 1)

EV1: ADDR = 1, the ADDR bit is cleared by reading the SR1 register first and then the SR2 register

EV3-1: TxE=1, shift register empty, data register empty, write Data1 in DR.

EV3: TxE=1, shift register not empty, data register empty, cleared by writing DR

EV3-2: AF = 1; The software writes 0 to the AF bit to clear the bit

Notes:

- 1) EV1 and EV3-1 events pull down the SCL until the end of the corresponding software sequence.
- 2) The software sequence of EV3 must be completed before the end of the current byte transfer

### 36.3.4.2 Slave receive mode

After receiving the address and clearing the ADDR, (if the lowest bit of the address byte is 0) slave will store the byte received from the SDA line into the DR register through the internal shift register. After each byte the interface generates in sequence:

- If the ACK bit is set, an answer pulse is generated
- Hardware settings RxNE = 1. An interrupt is generated if the ITEVTEN and ITBUFEN bit is set.

If RxNE is set and the DR register is not read until the end of the reception of new data, the BTF bit is set and slave keeps pulling down the SCL until the BTF is cleared (reading the I2C\_DR register after reading the I2C\_SR1). (See figure below).

Transmission sequence diagram 36-4 from receiver

**Description:** S = Start, SR = Repeated Start, P = Stop, A = Acknowledge, NA = Non-acknowledge, EVx = Event (interrupt when ITEVFEN = 1)

**EV1:** ADDR = 1, the ADDR is cleared by reading SR1 first and then reading SR2

**EV2:** RxNE=1 cleared by reading DR register

**EV4:** STOPF=1, cleared by reading SR1 register followed by writing to the CR1 register.

Notes:

- 1) The EV1 event pulls down the SCL until the end of the corresponding software sequence.
- 2) The EV2 software sequence must be completed before the current byte transfer is complete.
- 3) When the user checks the contents of the SR1 register, a complete clear sequence should be performed for each set flag bit. Thus, for ADDR and STOPF flags, the following sequence is required inside the I2C interrupt routine:

If ADDR = 1, reading SR1 followed by reading SR2; if STOPF = 1, reading SR1 followed by reading CR1.

The purpose is to make sure that both ADDR and STOPF flags are cleared if both are found set.

### 36.3.4.3 Closing slave communication

After the last data byte is transferred, a Stop Condition is generated by the master. The interface detects this condition and sets:

- The hardware sets STOPF and generates an interrupt if the ITEVTEN bit is set.

The STOPF bit is cleared by a read of the SR1 register followed by a write to the CR1 register.

### 36.3.5 Master mode of I2C

In Master mode, the I2C interface initiates a data transfer and generates the clock signal. A serial data transfer always begins with a start condition and ends with a stop condition.

Master mode is selected as soon as the Start condition is generated on the bus with a START bit.

The following is the required sequence in master mode:

- Program the peripheral input clock in I2C\_CR2 register in order to generate correct timings
- Configure the clock control registers
- Configure the rise time register
- Program the PE bit in I2C\_CR1 register to enable the peripheral
- Set the START bit in the I2C\_CR1 register to generate a Start condition

The peripheral input clock frequency must be at least:

- 2 MHz in Sm mode
- 4 MHz in Fm mode
- In Fast mode plus: 16MHz

#### 36.3.5.1 SCL master clock generation

The CCR register counts with the rising edge of the input clock, generating the high and low levels of the SCL. As a slave may stretch the SCL line, the peripheral checks the SCL input from the bus at the end of the time programmed in I2C\_TRISE register after rising edge generation.

- If the SCL line is low, it means that a slave is stretching the bus, and the high level counter stops until the SCL line is detected high. This allows to guarantee the minimum HIGH period of the SCL clock parameter.
- If the SCL line is high, the high level counter keeps on counting.

Indeed, the feedback loop from the SCL rising edge generation by the peripheral to the SCL rising edge detection by the peripheral takes time even if no slave stretches the clock. This loopback duration is linked to the SCL rising time, plus delay due to the noise filter present on the SCL input path, plus delay due to internal SCL input synchronization with APB clock. The maximum time of the feedback loop is set in the TRISE register, so the frequency of the SCL remains stable regardless of the SCL rise time.

#### 36.3.5.2 Start condition

Setting the START bit causes the interface to generate a Start condition and to switch to Master mode (MSL bit set) when the BUSY bit is cleared.

Note: Setting the START bit in host mode will generate a restart condition by the hardware after the current byte transfer is completed.

Once the Start condition is sent:

- The SB bit is set by hardware, and if the ITEVTEN bit is set, an interrupt is generated.
- The master reads the I2C\_SR1 register and writes the slave address to the I2C\_DR register.

#### 36.3.5.3 Slave address transmission

Then the slave address is sent to the SDA line via the internal shift register.

- In 10-bit address mode, sending a header sequence produces the following events:

The ADD10 bit is set by hardware, and if the ITEVFEN bit is set, an interrupt is generated.

The host then reads the SR1 register and writes the second address byte to the DR register.

- The ADDR bit is set by hardware, and if the ITEVFEN bit is set, an interrupt is generated.

The host then reads the SR1 register and then the SR2 register.

- In 7-bit address mode, an address byte will be sent out.

Once the address byte is sent out,

- The ADDR bit is set by hardware, and if the ITEVFEN bit is set, an interrupt is generated.

The master then waits for a read of the SR1 register, followed by a read of the SR2 register.

According to the lowest bit of the outgoing slave address, the master device decides whether to enter the transmitter mode or the receiver mode.

- In 7-bit address mode,

- To enter transmitter mode, the master device sends the slave address so that the lowest bit is equal to 0.

- To enter receiver mode, the master device sends the slave address so that the lowest bit is equal to 1.

- In 10-bit address mode

- To enter transmitter mode, the master device first sends the header byte (11110xx0), and then sends the slave address with the lowest bit equal to 0. (The xx in the header byte is the highest 2 bits of the 10-bit address.)

- To enter receiver mode, the master device first sends the header byte (11110xx0), and then sends the slave address with the lowest bit equal to 1. A start condition is then retransmitted, followed by the header byte (11110xx1). (xx in the header byte is the highest 2 bits of the 10-bit address).

The TRA bit indicate whether the master device is in receiver mode or transmitter mode

#### 36.3.5.4 Host send mode

After sending the address and clearing the ADDR bit, the host sends the data bytes from the DR register to the SDA line through the internal shift register.

The host waits until the first data byte is written to the DR register (see EV8\_1).

When the acknowledge pulse is received, the TxE bit is set by hardware and an interrupt is generated if the ITEVFEN and ITBUFEN bits are set.

If TxE is set and some data were not written in the DR register before the end of the next data transmission, the BTF bit is set. The interface waits until BTF is cleared by a read from I2C\_SR1 followed by a write to I2C\_DR, stretching SCL low.

#### Closing slave communication

After the last byte is written in the DR register, a STOP condition is generated by setting the STOP bit (see EV8\_2 in Figure), and then the I2C interface will automatically return to slave mode (MSL bit clear).

Note: Stop condition should be programmed during EV8\_2 event, when either TxE or BTF is set.

Figure 36-5 Transfer sequence diagram for master transmitter

**Description:** S = Start, SR = Repeated Start, P = Stop, A = Acknowledge, NA = Non-acknowledge, EVx = Event (interrupt when ITEVFEN = 1)

**EV5:** SB = 1, cleared by reading SR1 register followed by writing DR register with Address.

**EV6:** ADDR = 1, read SR1, read SR2 again, clear the event

**EV8\_1:** TXE = 1, shift register empty

**EV8:** TXE = 1, cleared by writing DR register

**EV8\_2:** TXE = 1, BTF = 1, cleared by hardware by the Stop condition

**EV9:** ADDR10 = 1, read SR1 and write DR register to clear the event

Notes:

The 1. EV5, EV6, EV8\_1 and EV8\_2 events stretch SCL low until the end of the corresponding software sequence.

The 2. EV8 software sequence must complete before the end of the current byte transfer. If the software sequence of EV8 cannot be completed before the end of the currently transmitted byte, BTF is recommended instead of TxE

### 36.3.5.5 Host Receive Mode

Following the address transmission and after clearing ADDR, the I2C interface enters Master Receiver mode. In this mode the interface receives bytes from the SDA line into the DR register via the internal shift register. After receiving each byte, the I2C interface performs the following operations in turn:

- If the ACK bit is set, an answer pulse is emitted.
- The RxNE bit is set and an interrupt is generated if the INEVFEN and ITBUFEN bits are set.

If the RxNE bit is set and the data in the DR register is not read before the end of the last data reception, the BTF bit is set by hardware and the interface waits until BTF is cleared by a read in the I2C\_SR1 register followed by a read in the I2C\_DR register, stretching SCL low.

#### Closing slave communication

**Method 1:** The application scenario of this method is that when the I2C interrupt is set to the highest priority in the application program

After receiving the last byte from the slave, the master sends a NACK. After receiving this NACK, the slave releases the control of the SCL and SDA lines. Then the master can send a Stop/Restart condition.

- 1) To generate the non-acknowledge pulse after the last received data byte, the ACK bit must be cleared just after reading the second last data byte (after second last RxNE event).

- 2) To generate the Stop/Restart condition, software must set the STOP/START bit just after reading the second last data byte (after the second last RxNE event).
- 3) When a single byte is received, the generation bit for clearing ACK and stop conditions should be just after EV6 (after clearing ADDR at EV6\_1). After the Stop condition generation, the interface goes automatically back to slave mode (MSL bit cleared).

Figure 36-6 Method 1: transfer sequence diagram for master receiver

**Description:** S = Start, SR = Repeated Start, P = Stop, A = Acknowledge, NA = Non-acknowledge, EVx = Event (interrupt when ITEVFEN = 1)

**EV5:** SB=1, cleared by reading SR1 register followed by writing DR register.

**EV6:** ADDR=1, cleared by reading SR1 followed by reading SR2

**EV6\_1:** no associated flag event, used for 1 byte reception only.

**EV7:** RxNE=1 cleared by reading DR register.

**EV7\_1:** RxNE=1 cleared by reading DR register, program ACK=0 and STOP request

**EV9:** ADD10 = 1, read SR1 and write DR register to clear the event

Notes:

- 1) If a single byte is received, it is NA.
- 2) The EV5 and EV6 events stretch SCL low until the end of the corresponding software sequence.
- 3) The EV7 software sequence must complete before the end of the current byte transfer. In EV7, if the software sequence cannot be executed before the currently transmitted byte transfer is completed, it is recommended to use BTF instead of RXNE.
- 4) The software sequence of EV6\_1 or EV7\_1 must be completed before the ACK bit of the current byte transmission is transmitted.

**Method 2:** The application scenario of this method is that the interrupt of I2C is not the highest priority in the application, or the query method is used

With this method, if DataN-2 is not read, after DataN-1, the communication will be stretched (both RxNE and BTF are set). Then, clear the ACK bit before reading DataN-2 in DR register to ensure it is cleared before the DataN Acknowledge pulse. After reading DataN-2, the STOP/START bits are set and DataN-1 is read. After RxNE is set, read DataN.

Figure 36-7 Method 2: transfer sequence diagram for master receiver when  $N > 2$ 

**Description:** S = Start, SR = Repeated Start, P = Stop, A = Acknowledge, NA = Non-acknowledge, EVx = Event (interrupt when ITEVFEN = 1)

**EV5:** SB = 1, read the SR1 register first, read the SR2 register first, then write the DR register, and clear this bit

**EV6:** ADDR, read SR1 first, then read SR2, clear this bit

**EV7:** RxNE=1 cleared by reading DR register

**EV7\_2:** BTF = 1, DataN-2 in DR register and DataN-1 in shift register, program ACK = 0, Read DataN-2 in DR. Program STOP = 1, read DataN-1.

**EV9:** ADD10 = 1, read SR1 and write DR register to clear the event

Notes:

- 1) The EV5 and EV6 events stretch SCL low until the end of the corresponding software sequence.
- 2) The EV7 software sequence must complete before the end of the current byte transfer. In EV7, if the software sequence cannot be executed before the currently transmitted byte transfer is completed, it is recommended to use BTF instead of RXNE.

• When 3 bytes are to be read away:

- RXNE = 1, DataN-2 Not reading.
- DataN-1 received
- BTF = 1, Shift and DR registers full. The DR register stores DataN-2 and the shift register stores DataN-1. At this time, the SCL is pulled low and there is no other data to be received on the bus
- Clear ACK bit
- Read DataN-2 in the DR register, which will start the reception of DataN by the shift register
- DataN received (with a NACK)
- Program START/STOP bit
- Read DataN-1
- RxNE=1
- Read DataN

The procedure described above is valid for  $N > 2$ . The cases where a single byte or two bytes are to be received should be handled differently, as described below:

- Case of 2 bytes received
  - Set POS and ACK bit
  - Wait for the ADDR flag to be set
  - Clear ADDR bit
  - Clear ACK bit
  - Wait for BTF to be set
  - Program STOP bit
  - Read DR twice

Figure 36-8 Method 2: transfer sequence diagram for master receiver when N=2

**Description:** S = Start, SR = Repeated Start, P = Stop, A = Acknowledge, NA = Non-acknowledge, EVx = Event (interrupt when ITEVFEN = 1)

**EV5:** SB=1, cleared by reading SR1 register followed by writing the DR register.

**EV6:** ADDR=1, cleared by reading SR1 followed by reading SR2

**EV6\_1:** No associated flag event. The acknowledge disable should be done just after EV6, that is after ADDR is cleared.

**EV7\_3:** BTF = 1, program STOP = 1, read DR twice (Read Data1 and Data2) just after programming the STOP.

**EV9:** ADDR10 = 1, read SR1 and write DR register to clear the event

**Notes:**

- 1) The EV5 and EV6 events stretch SCL low until the end of the corresponding software sequence.
- 2) The software sequence of EV6\_1 must be completed before the ACK bit of the current byte transmission is sent.

- Case of single byte reception
  - In the ADDR event, clear the ACK bit
  - Clear ADDR
  - Program STOP/START bit
  - Read the data after the RxNE flag is set.

Figure 36-9 Method 2: transfer sequence diagram for master receiver when N=1

**Description:** S = Start, SR = Repeated Start, P = Stop, A = Acknowledge, NA = Non-acknowledge, EVx = Event (interrupt when ITEVFEN = 1)

**EV5:** SB=1, cleared by reading SR1 register followed by writing the DR register.

**EV6\_3:** ADDR = 1, program ACK = 0. Clear ADDR by reading SR1 register followed by reading SR2 register. Program STOP =1 just after ADDR is cleared.

**EV7:** RxNE=1 cleared by reading DR register

**EV9:** ADD10 = 1, read SR1 and write DR register to clear the event

Notes:

EV5, EV6, EV8\_1, and EV8\_2 events stretch the low level of the SCL until the end of execution of the corresponding software sequence.

### 36.3.6 Error flags

#### Bus error (BERR)

This error occurs when the I2C interface detects an external Stop or Start condition during an address or a data transfer. In this case:

- BERR Bit is set to '1'; If the ITERREN bit is set, an interrupt is generated;
- In slave mode: the data is discarded and the hardware releases the bus.
  - In case of a misplaced Start, the slave considers it is a restart and waits for an address, or a Stop condition
  - In case of a misplaced Stop, the slave behaves like for a Stop condition and the lines are released by hardware
- In host mode: The hardware does not release the bus and does not affect the current transmission state. It is up to the software to abort or not the current transmission.

#### Answer Failure (AF)

This error occurs when the interface detects a non-acknowledge bit. In this case:

- The AF bit is set and if the ITERREN bit is set, an interrupt is generated
- When the transmitter receives a NACK, the communication must be reset.

- If in slave mode, hardware releases the bus
- If in host mode, the software must generate a stop condition or restart

#### **Arbitration Loss (ARLO)**

This error occurs when the I2C interface detects an arbitration lost condition. In this case:

- The ARLO bit is set by hardware, and if the ITERREN bit is set, an interrupt is generated
- The I2C interface automatically returns to slave mode (the MSL bit is cleared). When the I2C loses the arbitration, it is not able to acknowledge its slave address in the same transfer, but it can acknowledge it after a repeated Start from the winning master.
- Hardware release bus

#### **Overload/Underload Error (OVR)**

An overrun error can occur in slave mode when clock stretching is disabled and the I2C interface is receiving data. The interface has received a byte (RxNE=1) and the data in DR register has not been read, before the next byte is received by the interface.

In this case:

- The last received data is discarded
- In the event of an overload error, the software shall clear the RxNE bit and the transmitter shall resend the last transmitted byte

Underrun error can occur in slave mode when clock stretching is disabled and the I2C interface is transmitting data. The interface has not updated the DR with the next byte (TxE=1), before the clock comes for the next byte. In this case:

- The previous byte in the DR register will be issued repeatedly
- The user should determine that in the event of an underload run error, the receiving end should discard repeatedly received data. The next bytes are written within the clock low time specified in the I2C bus standard.

For the first byte to be transmitted, the DR must be written after ADDR is cleared and before the first SCL rising edge. If not possible, the receiver must discard the first data.

### **36.3.7 DMA functionality**

The DMA request (when enabled) is used only for data transmission. DMA requests are generated by data register becoming empty in transmission and data register becoming full in reception. The DMA must be initialized and enabled before the I2C data transfer. The DMAEN bit must be set in the I2C\_CR2 register before the ADDR event.

In master or slave mode, when the clock extension function is enabled, DMAEN can be set during the ADDR event before the ADDR is cleared. The DMA request must be served before the end of the current byte transfer. When the DMA transmission data length reaches the value set by DMA, the DMA controller sends an EOT (End of transfer) to the I2C and generates a transmission completion interrupt (if the interrupt enable bit is valid):

- Host send mode: In the EOT interrupt service routine, DMA requests need to be prohibited, and then the STOP condition needs to be set after waiting for the BTF event.

●Host acceptance mode: When the number of data to be received is greater than or equal to 2, the DMA controller sends a hardware signal EOT\_1 (corresponding to the number of DMA transmission bytes-1). If, in the I2C\_CR2 register, the LAST bit is set, I2C automatically sends a NACK after the next byte following EOT\_1. The user can generate a Stop condition in the DMA transfer complete interrupt routine if enabled.

### 36.3.8 Support wakeup from STOP mode

When the MCU is in STOP mode, the address can be received through I2C. If the address matches, the MCU can be awakened, otherwise, the STOP state can be maintained.

- 1) To implement the above functions, it is necessary to enable the PE and WUPEN of I2C\_CR1 before entering the STOP mode, and to enable the clock of I2C in the RCC.
- 2) The STOP mode wake-up process also supports a configurable timeout time, which can be configured by setting WKUP\_CNT and WKUP\_DIV of I2C\_CR1, wakes up the MCU after generating timeout if ITERREN is enabled, and maintains the STOP state after generating timeout if ITERREN is not enabled.
- 3) Before entering STOP mode, I2C\_CR1 needs to be reasonably configured according to the current communication speed. WKUP\_CNT and I2C\_CR1.WKUP\_DIV, otherwise it will result in timeout and the address cannot be matched.

### 36.3.9 Interrupts and events

Table 36-1 I<sup>2</sup>C interrupt requests

| Interrupt event                                | Event flag                   | Enable control bit  |
|------------------------------------------------|------------------------------|---------------------|
| Start bit sent (Master)                        | SB                           | ITEVTEN             |
| Address sent (Master) or address match (Slave) | ADDR                         |                     |
| ADD10                                          | 10-bit header sent (primary) |                     |
| Slave Received                                 | STOPF                        |                     |
| Data byte transfer finished                    | BTF                          |                     |
| Receive buffer not empty                       | RxNE                         | ITEVTEN and ITBUFEN |
| Transmit buffer empty                          | TxE                          |                     |
| Bus error (BERR)                               | BERR                         | ITERREN             |
| Arbitration Lost (Master)                      | ARLO                         |                     |
| Acknowledge failure                            | AF                           |                     |
| Overrun/Underrun                               | OVR                          |                     |
| PEC error                                      | PECERR                       |                     |
| Timeout/Tlow error                             | TIMEOUT                      |                     |
| SMBus Alert                                    | SMBALERT                     |                     |

#### 36.3.10 System management bus SMBus

The System Management Bus (SMBus) is a two-wire interface. Through it, various devices can communicate with each other and with the rest of the system. It is based on I2C operating principles. SMBus provides a control bus for system and power management-related tasks. A system using SMBus can communicate information with multiple devices without the need to use separate control lines.

The System Management Bus (SMBus) standard relates to three categories of devices. Slave device: The device that receives or responds to the command. Master: The device used to issue orders, generate clocks, and terminate transmissions. Host: is a dedicated master device that provides the main interface with the system CPU. The master must have master-slave functionality and must support the SMBus reminder protocol. Only one host is allowed in a system.

Using the system management bus, the device can provide manufacturer information, tell the system its model/part number, save the status of suspended events, report different types of errors, receive control parameters, and return its status. SMBus provides a control bus for system and power management-related tasks.

The I2C module of this product supports SMBus/PMbus functionality.

Table 36-2 Differences between SMBus and I2C Comparison:

| SMBus                                                      | I2C                                                |
|------------------------------------------------------------|----------------------------------------------------|
| Maximum speed 100 kHz                                      | Maximum speed 400 kHz                              |
| Minimum clock speed 10 kHz                                 | No minimum clock speed                             |
| 35 ms clock low timeout                                    | No timeout                                         |
| Logic levels are fixed                                     | Logic levels are VCC dependent                     |
| Different address types (reserved, dynamic, etc.)          | 7-bit, 10-bit and general call slave address types |
| Different bus protocols (quick command, process call etc.) | No bus protocols                                   |

Similarities between SMBus and I2C:

- Two-line bus protocol (1 clock, 1 data) + optional SMBus reminder line
- Master-slave communication, master device provides clock
- Multi-host function
- The SMBus data format is similar to I2C's 7-bit address format

#### 36.3.10.1 Address resolution protocol (ARP)

SMBus slave address conflicts can be resolved by dynamically assigning a new unique address to each slave device.

ARP has the following properties:

- Address allocation uses standard SMBus physical layer arbitration mechanism
- While the device maintains power, the assigned address remains the same, allowing the device to retain its address when the power is lost.
- After address allocation, there is no additional SMBus packaging overhead (that is, the device accessing the allocated address takes the same time as the device accessing the fixed address).
- Any SMBus master device can traverse the bus.

#### 36.3.10.2 SMBus alert mode

The SMBus reminder is an optional signal with an interrupt line for devices that want to expand their control capabilities at the expense of one pin. SMBALERT, like SCL and SDA signals, is a line and signal. SMBALERT is commonly used with SMBus broadcast call address. Messages related to SMBus are 2 bytes.

A device with only slave functionality can signal to the master that it wishes to communicate via SMBALERT by setting the ALERT bit on the I2C\_CR1 register. The host processes the interrupt and accesses all SMBALERT devices via an Alert Response Address (ARA) (address value 0001100x). Only the device(s) which pulled SMBALERT low will acknowledge the alert response address. This status is identified using SMBALERT Status flag in I2C\_SR1 register. The host performs a modified receive byte operation. The 7 bit device address provided by the slave transmit device is placed in the 7 most significant bits of the byte. The eighth bit can be a zero or one.

If multiple devices pull SMBALERT low, the highest priority device (the smallest address) will win communication rights through standard arbitration during address transmission. After confirming the slave

address, the device does not need to pull down its SMBALERT again. If the host still sees that SMBALERT is low after the message transmission is completed, it knows that it needs to read the ARA again.

Hosts that do not implement the SMBALERT signal can access ARA periodically.

### 36.3.10.3 Timeout error

There are many differences between I2C and SMBus in timing specifications.

SMBus defines a clock low timeout, TIMEOUT of 35 ms. SMBus specifies that TLOW: SEXT is the cumulative clock low expansion time of the slave device. SMBus specifies that TLOW: MEXT is the accumulated clock low expansion time of the master device. For more timeout details, please refer to version 2.0 of the SMBus specification (<http://smbus.org/specs/>). The status flag TIMEOUT error in I2C\_SR1 indicates the status of this feature.

### 36.3.10.4 Interfaces using SMBus mode

TIMOUTEN and TEXTEN positions 1 in the I2C\_TIMEOUTR register are used to enable timeout detection. The timer must be programmed in such a way that a timeout condition is detected before the maximum time specified by the SMBus specification.

#### tTIMEOUT inspect

To enable the tTIMEOUT check, the 12-bit TIMEOUTA [11: 0] bit must be programmed as a timer overload value to check the tTIMEOUT parameter. The TIDLE bit must be configured to "0" to detect an SCL low timeout.

The timer is then enabled by placing the TIMOUTEN position 1 in the I2C\_TIMEOUTR register.

If the low duration of the SCL exceeds  $(\text{TIMEOUTA} + 1) \times 2048 \times \text{tPCLK}$ , the TIMEOUT flag of the I2C\_SR1 register will be set to 1.

(max tTIMEOUT = 25 ms).

Note: At TIMOUTEN position 1, it is not allowed to change the configuration of the TIMEOUTA [11: 0] bit and the TIDLE bit.

#### • tLOW: SEXT and tLOW: MEXT check

The TIMEOUTB timer must be configured to verify tLOW: SEXT for the slave and tLOW: MEXT for the master depending on whether the peripheral is configured as the master or the slave. As the standard specifies only a maximum, the user can choose the same value for the both.

The timer is then enabled by putting the TEXTEN position 1 in the I2C\_TIMEOUTR register.

If the accumulation time of the SMBus peripheral extension SCL exceeds  $(\text{TIMEOUTB} + 1) \times 2048 \times \text{tPCLK}$ , the TIMEOUT flag in the I2C\_SR1 register will be set to 1.

See below: Example TIMEOUTB settings at different PCLK frequencies.

NOTE: Changes to the TIMEOUTB configuration are not allowed at TEXTEN position 1.

### 36.3.10.5 Bus idle detection

To enable tIDLE checking, the 12-bit TIMEOUTA [11: 0] field must be programmed as a timer overload value to get the tIDLE parameter. The TIDLE bit must be configured to "1" to detect SCL and SDA high timeouts.

The timer is then enabled by placing the TIMOUTEN position 1 in the I2C\_TIMEOUTR register.

If the high level duration of the SCL and SDA lines exceeds  $(\text{TIMEOUTA}+1) \times 4 \times \text{tPCLK}$ , the TIMEOUT flag in the I2C\_SR1 register will be set to 1.

See Table: Examples of TIMEOUTA settings at different PCLK frequencies (maximum tIDLE = 50  $\mu$ s).

Note: When TIMEOUTEN is set to 1, it is not allowed to change the TIMEOUTA and tIDLE configuration.

### 36.3.10.6 PMbus

PMBus is based on SMBus, and the transmission logic is exactly the same as SMBus. The difference is that PMbus defines some functions related to power management (done by software).

### 36.3.10.7 SMBus: I2C\_TIMEOUTR Register Configuration Example

This section is relevant only when SMBus feature is supported.

- Configure the maximum duration of tTIMEOUT to 25 ms:

Table 36-3 Example TIMEOUTA settings at different PCLK frequencies (maximum tTIMEOUT = 25 ms)

| fPCLK  | TIMEOUTA [11: 0] | tIDLE | TIMEOUTEN | tTIMEOUT                                                  |
|--------|------------------|-------|-----------|-----------------------------------------------------------|
| 8 MHz  | 0x61             | 0     | 1         | $98 \times 2048 \times 125 \text{ ns} = 25 \text{ ms}$    |
| 16 MHz | 0xC3             | 0     | 1         | $196 \times 2048 \times 62.5 \text{ ns} = 25 \text{ ms}$  |
| 32 MHz | 0x186            | 0     | 1         | $391 \times 2048 \times 31.25 \text{ ns} = 25 \text{ ms}$ |
| 48 MHz | 0x249            | 0     | 1         | $586 \times 2048 \times 20.08 \text{ ns} = 25 \text{ ms}$ |

- Configure the maximum duration of tLOW: SEXT and tLOW: MEXT to 8 ms:

Table 36-4 Example TIMEOUTB settings at different PCLK frequencies

| fPCLK  | TIMEOUTB [11: 0] | TEXTEN | tLOW: EXT                                                |
|--------|------------------|--------|----------------------------------------------------------|
| 8 MHz  | 0x1F             | 1      | $32 \times 2048 \times 125 \text{ ns} = 8 \text{ ms}$    |
| 16 MHz | 0x3F             | 1      | $64 \times 2048 \times 62.5 \text{ ns} = 8 \text{ ms}$   |
| 48 MHz | 0xBB             | 1      | $188 \times 2048 \times 20.08 \text{ ns} = 8 \text{ ms}$ |

- Configure the maximum duration of tIDLE to 50  $\mu$ s:

Table 36-5 Example TIMEOUTA settings at different PCLK frequencies (maximum tIDLE = 50  $\mu$ s)

| fPCLK  | TIMEOUTB [11: 0] | tIDLE | TIMEOUTEN | tIDLE                                                   |
|--------|------------------|-------|-----------|---------------------------------------------------------|
| 8 MHz  | 0x63             | 1     | 1         | $100 \times 4 \times 125 \text{ ns} = 50 \mu\text{s}$   |
| 16 MHz | 0xC7             | 1     | 1         | $64 \times 4 \times 62.5 \text{ ns} = 50 \mu\text{s}$   |
| 48 MHz | 0x257            | 1     | 1         | $600 \times 4 \times 20.08 \text{ ns} = 50 \mu\text{s}$ |

Table 36-6 SMBus Timeout Specification

| Symbol            | Parameter                                    | Limits |     | Unit          |
|-------------------|----------------------------------------------|--------|-----|---------------|
|                   |                                              | Min    | Max |               |
| tTIMEOUT          | Detect clock low timeout                     | 25     | 35  | ms            |
| tLOW: SEXT<br>(1) | Cumulative Clock Low Extension Time (Slave)  | -      | 25  | ms            |
| tLOW: MEXT<br>(2) | Cumulative Clock Low Extension Time (Master) | -      | 10  | ms            |
| tIDLE             | SCL and SDA high timeout                     | -      | 50  | $\mu\text{s}$ |

1. tLOW: SEXT is a cumulative period of time, i.e., a given period of time that the clock signal can extend from the initial start of a message to the stop of the device. Other slave devices or master devices may also extend the clock, which in turn causes the total extension of the clock low level to exceed tLOW: SEXT. Therefore, this device should be the only device addressed by the full-speed master device when measuring this parameter.
2. tLOW: MEXT is an accumulated period of time, that is, the time that the clock signal of the master device can extend within each byte of the message (defined as START to ACK, ACK to ACK, or ACK to STOP). The slave device or other master device may also extend the clock, which in turn

causes the total time of the clock low to exceed tLOW: MEXT (for a given byte). Therefore, the full-speed master only addresses one slave when measuring this parameter.

## 36.4 TIMx registers

The peripheral registers have to be accessed by half-words (16 bits) or words (32 bits).

### 36.4.1 I2C Control Register 1(I2C\_CR1)

|    |           |    |   | Note: PEC calculation is corrupted by an arbitration loss.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                     |
| 11 | POS       | RW | 0 | <p>ACK/PEC (for data reception). This bit is set and cleared by software and cleared by hardware when PE=0.</p> <p>0: ACK bit controls the (N)ACK of the current byte being received in the shift register. The PEC bit indicates that current byte in shift register is a PEC.</p> <p>1: ACK bit controls the (N)ACK of the next byte which will be received in the shift register. The PEC bit indicates that the next byte in the shift register is a PEC.</p> <p>Note: The POS bit is used when the procedure for reception of 2 bytes is followed. It must be configured before data reception starts. To NACK the 2nd byte, the ACK bit must be cleared just after ADDR is cleared. In order to detect the PEC of the 2nd byte, the PEC bit must be set at the ADDR extension event after the POS bit is configured.</p> |

| 11: 7  | THOLDDATA     | RW  | 5'h1        | Maximum data holding time in fast/standard/fast enhancement mode (transmission mode)<br>These bits are used for the minimum time to guarantee the data holding time in the data transmission mode.<br>For example: The maximum SDA drop time allowed for standard mode is 300ns. If the value of I2C_CR2.FREQ [6: 0] is equal to 0x08 and Tpclk = 125ns, 0x03 is configured in TRISE<br>(300ns/125ns = 2.4 + 1 = 3.4)<br>If the result is not an integer, the integer part is written to THOLDDATA to ensure configuration.                                                                                                                                                                                                                                                  |
| 6: 0   | TRISE         | RW  | 7'h2        | Maximum rise time in Fm/Sm mode (Master mode)<br>These bits should provide the maximum duration of the SCL feedback loop in master mode. The purpose is to keep a stable SCL frequency whatever the SCL rising edge duration. These bits must be programmed with the maximum SCL rise time given in the I2C bus specification, incremented by 1.<br>For instance: in Sm mode, the maximum allowed SCL rise time is 1000 ns. If the value of I2C_CR2.FREQ [5: 0] is equal to 0x08 and Tpclk = 125ns, 0x09 is configured in TRISE (1000ns/125ns = 8 + 1 = 9).<br>If the result is not an integer, TRISE[5:0] must be programmed with the integer part, in order to respect the tHIGH parameter.<br>Note: TRISE[5:0] must be configured only when the I2C is disabled (PE = 0). |

## 37. Universal Synchronous Transceiver (USART)

### 37.1 Introduction

Universal Synchronous Asynchronous Transceiver (USART) can flexibly exchange full-duplex data with external devices, meeting the requirements of external devices for industrial standard NRZ asynchronous serial data format. The USART utilizes a fractional baud rate generator to provide a wide range of baud rate options.

Supports synchronous unidirectional communication and half-duplex single-wire communication, and also supports LIN (local Internet), smart card protocol and IrDA (infrared data organization) specifications, as well as modem (CTS/RTS) operation. It also supports multiprocessor communications.

High-speed data communication can be achieved by using the DMA method of the multi-buffer configuration.

### 37.2 Main Features

- Full-duplex asynchronous communication
- Configurable 16 or 8 oversampling methods to achieve the best choice between speed and clock tolerance
- Two built-in fifos for sending and receiving
- Both FIFO can be enable and provide status bits by software
- Dual clock domain: A USART\_CLK clock that exists in addition to PCLK
- Automatic baud rate detection function
- Configurable data word length (7-bit, 8-bit or 9-bit)
- Configurable data transmission direction: MSB, LSB
- Configurable stop bits-0.5, 1, 1.5 or 2 stop bits are supported
- Provides input and output function in synchronous mode
- Configurable multi-buffer communication using DMA (Direct Memory Access)
- Single-wire Half-duplex communications
- Separate enable bits for transmitter and receiver
- Configurable TX/RX pin signal
- Supported hardware flow control: modem and RS485
- Communication control and error detection signal
- Parity control
  - Send check digit
  - Check the received data
- Multiprocessor communication. enter into mute mode if address match does not occur.
  - Wake up in silent mode (by idle bus detection or address flag detection)
  - Wake-up mode of receiver: address bit (MSB, bit 9), bus idle

### 37.2.1 USART Extended Functions

- Ability of LIN master to send synchronous disconnected frames and ability of LIN slave to detect disconnected frames
  - Ability to generate 13-bit broken frames and detect broken frames when USART hardware is configured as LIN
- IRDA SIR encoder/decoder
- Smart card emulation function
  - Smart card interface supports asynchronous smart card protocol defined in ISO7816-3 standard
  - Smart card uses 0.5 and 1.5 stop bits
- MODBUS Communications
  - TIMOUT function
  - CR/LF character recognition function

### 37.2.2 USART Functional Block Diagram

Figure 37-1 USART block diagram

USART has two clock domains, one is PCLK and the other is USART\_CLK: There is no requirement for the speed of USART\_CLK and PCLK. The only requirement is that the software manages communication as fast as possible.

An idle symbol is regarded as a complete data frame consisting entirely of '1', followed by the start bit of the next frame containing the data (the number of bits of '1' also includes the number of bits of the stop bit).

A disconnected frame is considered to have received '0' throughout one frame period (including during the stop bit, also '0'). At the end of the disconnect frame, the transmitter inserts 2 more stop bits ('1') in response to the start bit.

Transmission and reception are driven by a common baud rate generator, which generates clocks for the transmitter and receiver when their enable bits are set respectively.

## 37.3 USART functional description

### 37.3.1 Transfer pin

#### 37.3.1.1 USART Features

Any USART bi-directional communication requires at least two pins: Receive Data Input (RX) and Send Data Output (TX).

RX: Receive data serial input. Data is recovered by oversampling techniques to distinguish data from noise.

TX: Transmit data output. When the transmitter is disabled, the output pin returns to its IO port configuration. When the transmitter is enabled but not sending data, the TX pin is high. In single-wire mode and smart card mode, this I/O port is used for both data transmission and reception.

#### 37.3.1.2 USART Hardware Flow Control

RS232 hardware flow control

CTS: Transmission starts at low level, and transmission ends to high level.

RTS: Low indicates that USART is ready to receive data.

RS485 hardware flow control

DE: This signal is used to control the transmission of an external receiver

#### 37.3.1.3 Sync mode and smart card mode

In synchronous master mode and smart card mode, the following pins are required:

CK: Transmitter clock output, in synchronous master mode, this pin outputs the transmitter data clock for synchronous transmission corresponding to SPI master mode (no clock pulses on the start and stop bits, and a software option to send clock pulses on the last data bit). In synchronous mode, data can be received synchronously on the RX pin. This mechanism can be used to control peripherals with shift registers (e.g., LCD drivers). The clock phase and polarity are software programmable.

### 37.3.2 USART Feature Description

The transmitter sends 7-bit, 8-bit, or 9-bit data depending on the status of the M-bit. When the transmit enable bit (TE) is set, the data in the transmit shift register is output on the TX pin and the corresponding clock pulse is output on the CK pin.

Notes:

1. In 7-bit data mode, smart card mode, LIN host mode is not supported.
2. The TE bit should not be reset during transmission of data. Resetting the TE bit during the transmission will corrupt the data on the TX pin as the baud rate counters will get frozen. The current data being transmitted will be lost.
3. An idle frame will be sent after the TE bit is enabled.
4. Every character is preceded by a start bit, which is a logic level low for one bit period. The character is terminated by a configurable number of stop bits.

5. The following stop bits are supported by USART: 0.5, 1, 1.5 and 2 stop bits.

Figure 37-2 word length programming

### 37.3.3 USART FIFO And threshold

USART can work in FIFO mode. USART has a transmit FIFO (TXFIFO) and a receive FIFO (RXFIFO). Enable FIFO mode by setting USART\_CR1. FIFOEN. This mode only supports UART, Sync Mode (Send) and Smart Card Mode TX.

Since the maximum data word length is 9 bits, the width of the TXFIFO is 9 bits. However, the default width of RXFIFO is 12 bits. This is because the receiver not only stores data in the FIFO, but also stores error flags (parity error, noise error, and frame error flags) associated with each character.

The received data is stored in the RXFIFO together with the corresponding flags. However, when reading the DR, only data is read. The status flag is available in the USART\_SR register. You can configure the TXFIFO and RXFIFO levels that trigger TX and RX interrupts. These thresholds are programmed by the RXFTCFG and TXFTCFG bits in USART\_CR1.

In this case, when the amount of data received by the RXFIFO reaches the threshold programmed in the RXFTCFG bit field, the RXFT flag is set in the USART\_CR3 register, generating the corresponding interrupt (if enabled).

When the number of empty positions in the TXFIFO reaches the threshold programmed in the TXFTCFG bit field, the TXFT flag is set in the USART\_CR3 register, generating the corresponding interrupt (if enabled).

Enable FIFO mode When data is received, the RXFNE bit is used to indicate that the RXFIFO is not empty. Read USART\_DR Returns the oldest data entered in the RXFIFO. When data is received, it is stored in the RXFIFO along with the corresponding error bit.

- In multiprocessor communication mode: When FIFO mode is disabled, the RXNE flag is set after each byte is received. When DMA reads the receive data register, it is cleared. When FIFO mode is enabled, the RXFNE flag is set when RXFIFO is not empty. After each DMA request, 1 data is received from the RXFIFO. A DMA request is triggered when the RXFIFO is not empty (there is data to read from the RXFIFO).

In single buffer mode:

When FIFO mode is disabled, clearing the RXNE flag is done by performing a software read from the USART\_DR register. The RXNE flag may also be cleared by setting the RXFRQ position at "1" at USART\_CR1. The RXNE flag must be cleared before the end of receiving the next character to avoid overflow errors.

When FIFO mode is enabled, RXFNE is set when RXFIFO is not empty. After each read operation from USART\_DR, a piece of data is retrieved from RXFIFO. When RXFIFO is empty, the RXFNE flag is cleared. When the RXFIFO is full, the first data in the RXFIFO must be read before the end of receiving the next character to avoid overflow errors. If the RXFNEIE bit is set, the RXFNE flag generates an interrupt.

#### 37.3.4 Transmitter

The transmitter can send data words of either 8 or 9 bits depending on the M bit status. When the transmit enable bit (TE) is set, the data in the transmit shift register is output on the TX pin and the corresponding clock pulse is output on the CK pin.

##### 37.3.4.1 Character transmission

During a USART transmission, data shifts out the least significant bit first on the TX pin. In this mode, the USART\_DR register consists of a buffer (TDR) between the internal bus and the transmit shift register.

Every character is preceded by a start bit, which is a logic level low for one bit period. The character is terminated by a configurable number of stop bits. The following stop bits are supported by USART: 1 and 2 stop bits.

Notes:

The TE bit should not be reset during transmission of data. Resetting the TE bit during the transmission will corrupt the data on the TX pin as the baud rate counters will get frozen. The current data being transmitted will be lost.

An idle frame will be sent after the TE bit is enabled.

##### 37.3.4.2 Configure stop bits

The number of stop bits to be transmitted with every character can be programmed in Control register 2, bits 13, 12.

- 1) 1 stop bit: The default value for the number of stop bits.
- 2) 2 stop bits: Can be used in regular USART mode, single wire mode, as well as modem mode.

An idle frame transmission will include the stop bits.

The break frame is a 10-bit low followed by a stop bit (when  $m = 0$ ); Or an 11-bit low followed by a stop bit (when  $m = 1$ ). It is not possible to transmit longer broken frames (longer than 10 or 11 bits in length).

Figure 37-3 Configurable Stop Bits

Procedure:

- 1) Enable the USART by writing the UE bit in USART\_CR1 register to 1.
- 2) Program the M bit in USART\_CR1 to define the word length.
- 3) Program the number of bits of the stop bit in USART\_CR2.
- 4) If multi-buffer communication is used, configure the DMA enable bit (DMAT) in USART\_CR3. Configure the DMA register as explained in multi-buffer communication.
- 5) Select the desired baud rate using the USART\_BRR register.
- 6) Set the TE bit in USART\_CR1 to send an idle frame as first transmission.
- 7) Write the data to be sent into the USART\_DR register (this action clears the TXE bit). Repeat this for each data to be transmitted in case of single buffer.
- 8) After writing the last data into the USART\_DR register, wait until TC=1. This indicates that the transmission of the last frame is complete. This is required for instance when the USART is disabled or enters the Halt mode to avoid corrupting the last transmission.

#### 37.3.4.3 Single-byte communication

The TXE bit is always cleared by a write to the data register. The TXE bit is set by hardware and it indicates:

- The data has been moved from TDR to the shift register and the data transmission has started.
- The TDR register is empty.
- The next data can be written in the USART\_DR register without overwriting the previous data.

This flag generates an interrupt if the TXEIE bit is set.

When a transmission is taking place, a write instruction to the USART\_DR register stores the data in the TDR register and which is copied in the shift register at the end of the current transmission.

When no transmission is taking place, a write instruction to the USART\_DR register places the data directly in the shift register, the data transmission starts, and the TXE bit is immediately set.

If a frame is transmitted (after the stop bit) and the TXE bit is set, the TC bit goes high. An interrupt is generated if the TCIE bit is set in the USART\_CR1 register.

After the last data word has been written in the USART\_DR register, you must wait for TC = 1 before turning off the USART module or setting the microcontroller into low power mode (see the figure below for details).

The TC bit is cleared by the following software sequence:

1. A read from the USART\_SR register;
2. A write to the USART\_DR register.

Note: The TC bit is cleared by writing 0 to it. This clearing sequence is recommended only for Multi-buffer communication.

Figure 37-4 TC/TXE behavior when transmitting

#### 37.3.4.4 Break characters

Setting the SBK bit transmits a break character. The break frame length depends on the Mbit. If the SBK bit is set to '1' a break character is sent on the TX line after completing the current character transmission. The SBK is reset by hardware upon completion of the disconnect character transmission (at the disconnect of the stop bit of the symbol). The USART inserts a logic 1 bit at the end of the last break frame to guarantee the recognition of the start bit of the next frame.

Note: If the software resets the SBK bit before the commencement of break transmission, the break character will not be transmitted. For two consecutive breaks, the SBK bit should be set after the stop bit of the previous break.

#### 37.3.4.5 Idle characters

Setting the TE bit drives the USART to send an idle frame before the first data frame.

### 37.3.5 Receiver

The USART can receive data words of either 8 or 9 bits depending on the M bit in the USART\_CR1 register.

#### 37.3.5.1 Start bit detection

In the USART, the start bit is detected when a specific sequence of samples is recognized. The sequence is 1 1 1 0 X 0 X 0 X 0 0 0

Figure 37-5 Start bit detection

If the sequence is incomplete, the receiving end will exit the start bit detection and return to the idle state (without setting the flag bit) waiting for the falling edge. The start bit is confirmed (RXNE flag set, interrupt generated if RXNEIE=1) if the 3 sampled bits are at 0 (first sampling on the 3rd, 5th and 7th bits finds the 3 bits at 0 and second sampling on the 8th, 9th and 10th bits also finds the 3 bits at 0). The start bit is validated (RXNE flag set, interrupt generated if RXNEIE=1) but the NE noise flag is set if, for both samplings, at least 2 out of the 3 sampled bits are at 0 (sampling on the 3rd, 5th and 7th bits and sampling on the 8th, 9th and 10th bits). If this condition cannot be met, the start bit detection process is aborted, and the receiver will return to the idle state (no flag bit is set).

If, for one of the samplings (sampling on the 3rd, 5th and 7th bits or sampling on the 8th, 9th and 10th bits), 2 out of the 3 bits are found at 0, the start bit is validated but the NE noise flag bit is set.

### 37.3.5.2 Character reception

During a USART reception, data shifts in least significant bit first through the RX pin. In this mode, the USART\_DR register consists of a buffer (RDR) between the internal bus and the received shift register. Procedure:

1. The UE of the USART\_CR1 register is set to 1 to activate USART.
2. Programming the M-bit definition word length of USART\_CR1
3. Write the number of stop bits in USART\_CR2
4. If multi-buffer communication is required, select the DMA enable bit (DMAR) in USART\_CR3. Configure the DMA register as explained in multi-buffer communication.
5. The desired baud rate is selected using the baud rate register USART\_BRR.
6. Set the RE bit of USART\_CR1. This enables the receiver which begins searching for a start bit.

When a character is received:

- The RXNE bit is set. It indicates that the content of the shift register is transferred to the RDR. In other words, data has been received and can be read (as well as its associated error flags).
- An interrupt is generated if the RXNEIE bit is set.
- The error flags can be set if a frame error, noise or an overrun error has been detected during reception.
- In multibuffer, RXNE is set after every byte received and is cleared by the DMA read to the Data register.
- In single buffer mode, clearing the RXNE bit is performed by a software read to the USART\_DR register. The RXNE flag can also be cleared by writing a zero to it. The RXNE bit must be cleared before the end of the reception of the next character to avoid an overrun error.

Note: The RE bit should not be reset while receiving data. If the RE bit is disabled during reception, the reception of the current byte will be aborted.

### 37.3.5.3 Break characters

When a break character is received, the USART handles it as a framing error

### 37.3.5.4 Idle characters

When an idle frame is detected, there is the same procedure as a data received character plus an interrupt if the IDLEIE bit is set.

### 37.3.5.5 Overrun error

An overrun error occurs when a character is received when RXNE has not been reset. Data can not be transferred from the shift register to the RDR register until the RXNE bit is cleared. The RXNE flag is set after every byte received. An overrun error occurs if RXNE flag is set when the next data is received or the previous DMA request has not been serviced.

When an overrun error occurs:

- The ORE bit is set.
- The RDR content will not be lost. The previous data is available when a read to USART\_DR is performed.
- The shift register will be overwritten. After that point, any data received during overrun is lost.
- An interrupt is generated if either the RXNEIE bit is set or both the EIE and DMAR bits are set.
- The ORE bit is reset by a read to the USART\_SR register followed by a USART\_DR register read operation.

Note: The ORE bit, when set, indicates that at least 1 data has been lost. There are two possibilities:

- If RXNE=1, then the last valid data is stored in the receive register RDR and can be read.
- If RXNE=0, then it means that the last valid data has already been read and thus there is nothing to be read in the RDR. This may occur when new (i.e. missing) data is received while the last valid data is read in the RDR. This may also occur when new data is received during a read sequence (between a USART\_SR register read access and a USART\_DR read access).

### 37.3.5.6 Noise error

Over-sampling techniques are used (except in synchronous mode) for data recovery by discriminating between valid incoming data and noise.

Figure 37-6 Data sampling for noise detection

Table 37-1 Noise detection from sampled data

| Sampled value | NE status | Received bit value | Data validity |
|---------------|-----------|--------------------|---------------|
| 000           | 0         | 0                  | Valid         |
| 001           | 1         | 0                  | Not Valid     |
| 010           | 1         | 0                  | Not Valid     |
| 011           | 1         | 1                  | Not Valid     |
| 100           | 1         | 0                  | Not Valid     |
| 101           | 1         | 1                  | Not Valid     |
| 110           | 1         | 1                  | Not Valid     |
| 111           | 0         | 1                  | Valid         |

When noise is detected in a frame:

- The NE is set at the rising edge of the RXNE bit.
- The invalid data is transferred from the Shift register to the USART\_DR register.
- No interrupt is generated in case of single byte communication. However this bit rises at the same time as the RXNE bit which itself generates an interrupt. In case of multibuffer communication an interrupt will be issued if the EIE bit is set in the USART\_CR3 register.
- The NE bit is reset by a USART\_SR register read operation followed by a USART\_DR register read operation.

### 37.3.5.7 Framing error

A framing error is detected when:

- The stop bit is not recognized on reception at the expected time, following either a desynchronization or excessive noise.
- When the framing error is detected:
  - The FE bit is set by hardware
  - The invalid data is transferred from the Shift register to the USART\_DR register.
  - No interrupt is generated in case of single byte communication. However, this bit rises at the same time as the RXNE bit which itself generates an interrupt. In case of multibuffer communication an interrupt is issued if the EIE bit is set in the USART\_CR3 register.
  - The FE bit is reset by a read to the USART\_SR register followed by a USART\_DR register read operation.

### 37.3.5.8 Configure stop bits on receive

Configurable stop bits during reception The number of received stop bits may be configured by the control bits of the control register 2, and may be 1 or 2 in the normal mode.

- 1 stop bit: sampling for 1 stop bit is done on the 8th, 9th and 10th samples.
- 2 stop bits: sampling for 2 stop bits is done on the 8th, 9th and 10th samples of the first stop bit.

The framing error flag is set if a framing error is detected during the first stop bit. The second stop bit is not checked for framing error. The RXNE flag is set at the end of the first stop bit.

#### Special frames and error handling:

Broken character: When a broken frame is received, USART treats it as an error frame.

Idle character: When an idle frame is detected, it is processed as a normal frame, and if IDLEIE = 1, an interrupt is generated.

#### Select the appropriate clock domain to:

The selection of clock source is controlled by RCC. Before enabling USART, the clock source must be selected.

The selection of clock source only takes into account two factors:

1. Do you need usart to be used in low power mode
2. Communication speed

You can configure the usart\_clk clock source in the RCC to achieve dual clocking. Otherwise, the usart\_clk clock is the same as the usart\_pclk clock.

Some USART\_clk sources enable USART to receive data while the MCU is in low power mode. Depending on the received data and the selected wake-up mode, the USART wakes up the MCU when needed to transmit the received data by performing a software read on the USART\_DR register or by DMA.

For other clock sources, the system must be operational to enable USART communication. The receiver implements different user-configurable oversampling techniques (except for synchronous mode) for data recovery by distinguishing incoming data from noise. This allows for a balance between maximum communication speed and noise/clock error immunity.

#### Noise error:

Data recovery is performed using oversampling techniques (except in synchronous mode) to distinguish valid input data from noise.

### 37.3.6 Fractional baud rate generation

The baud rates of the receiver and transmitter should be set to the same values in the integer and decimal registers of USARTDIV.

1: 16-bit oversampling mode

$$\text{Tx/Rx baud rate} = \frac{f_{ck}}{(16 * \text{USARTDIV})}$$

Here the fCK is the clock given to the peripheral.

Note: The baud counters are updated with the new value of the Baud registers after a write to USART\_BRR. Hence, the Baud rate register value should not be changed during communication.

Table 37-2 Error calculation when setting baud rate

| Baud rate |       | fck = 8MHZ |                                            |            | fck = 36MHZ |                                            |            | fck = 100MHZ |                                            |         |
|-----------|-------|------------|--------------------------------------------|------------|-------------|--------------------------------------------|------------|--------------|--------------------------------------------|---------|
| No.       | kbps  | Actual     | Value programmed in the baud rate register | Error %    | Actual      | Value programmed in the baud rate register | Error %    | Actual       | Value programmed in the baud rate register | Error % |
| 1         | 2.4   | 2.400      | 208.375                                    | 0.02 %     | 2.400       | 937.5                                      | 0.00 %     | 2.39998      | 2604.1875                                  | 0.00 %  |
| 2         | 9.6   | 9.604      | 52.0625                                    | 0.04 %     | 9.600       | 234.375                                    | 0.00 %     | 9.59417      | 651.4375                                   | 0.06 %  |
| 3         | 19.2  | 19.198     | 26.04375                                   | 0.01 %     | 19.200      | 117.1875                                   | 0.00 %     | 19.2012      | 325.5000                                   | 0.01 %  |

| 5         | 115.2 | 115.942    | 4.3125                                     | 0.64 %     | 115.385     | 19.5                                       | 0.16 %     | 115.207      | 54.2500                                    | 0.01 %  |
| 6         | 230.4 | 228.571    | 2.1875                                     | 0.80 %     | 230.769     | 9.75                                       | 0.16 %     | 230.415      | 27.1250                                    | 0.01 %  |
| 7         | 460.8 | 470.588    | 1.0625                                     | 2.08 %     | 461.538     | 4.875                                      | 0.16 %     | 460.829      | 13.5625                                    | 0.01 %  |
| 8         | 921.6 |            | Impossible                                 |            | 923.077     | 2.4375                                     | 0.16 %     | 925.926      | 6.7500                                     | 0.47 %  |
| 9         | 2250  |            | Impossible                                 |            | 2250.000    | 1                                          | 0.00 %     | 2272.73      | 2.7500                                     | 1.00 %  |
| 10        | 4500  |            | Impossible                                 | Impossible | Impossible  | Impossible                                 | Impossible | 4545.45      | 1.3750                                     | 1.00 %  |

Notes:

1. The lower the clock frequency of the CPU, the lower the error at a particular baud rate. The upper limit of the achievable baud rate can be fixed with this data.

2: 8-bit oversampling mode

$$\text{Tx/Rx baud rate} = \frac{f_{ck}}{(8 * USARTDIV)}$$

3. Do not use a frequency division factor less than 1

### 37.3.7 USART Receiver Tolerance Clock Changes

The USART asynchronous receiver operates correctly only if the total clock system deviation is less than the tolerance of the USART receiver. The causes which contribute to the total deviation are:

- DTRA: Variation due to transmitter error (including variation of transmitter-side oscillator)
- DQUANT: Error caused by receiver-side baud rate rounding
- DREC: Receiver Side Oscillator Changes
- DTCL: Variation due to transmission line (usually due to inconsistency between transceiver conversion timing from low to high and conversion timing from high to low).

Need to meet: DTRA + DQUANT + DREC + DTCL < USART receiver tolerance

Table 37-3 USART receiver tolerance when DIV\_Fraction is 0

| M bit | over8 = 0      |        |                 |        | over8 = 1      |        |                 |        |
|-------|----------------|--------|-----------------|--------|----------------|--------|-----------------|--------|
|       | NF is an error |        | NF doesn't care |        | NF is an error |        | NF doesn't care |        |
| 00    | 3.83%          | -2.71% | 3.79%           | -5.90% | 1.16%          | -4.50% | 1.16%           | -5.93% |
| 01    | 3.63%          | -4.57% | 4.17%           | -5.06% | 2.35%          | -3.73% | 3.18%           | -4.99% |
| 10    | 3.91%          | -2.86% | 4.17%           | -6.30% | 2.78%          | -5.56% | 1.39%           | -6.25% |

Table 37-4 USART receiver tolerance when DIV\_Fraction is not 0

| M bit | over8 = 0      |        |                 |        | over8 = 1      |        |                 |        |
|-------|----------------|--------|-----------------|--------|----------------|--------|-----------------|--------|
|       | NF is an error |        | NF doesn't care |        | NF is an error |        | NF doesn't care |        |
| 00    | 3.07%          | -2.08% | 3.78%           | -5.62% | 0.89%          | -4.05% | 1.34%           | -5.73% |

### 37.3.8 USART Auto baud rate detection

#### ● Auto baud rate detection

USART can automatically detect the baud rate based on the received characters and configure the baud rate register USART\_BRR.

Automatic baud rate detection is suitable for the following situations:

The system communication speed is unknown in advance;

The system uses a less accurate clock source, a mechanism that allows the correct baud rate to be obtained without measuring the clock deviation;

The clock source frequency must be compatible with the desired communication speed:

The baud rate for 1.16 bit oversampling must be between  $f_{CK}/65535$  and  $f_{CK}/16$ .

The baud rate for 2.8-bit oversampling must be between  $f_{CK}/65535$  and  $f_{CK}/8$ .

Configure the automatic baud rate detection mode via USART\_CR2. ABRMOD. There are 2 modes based on different character patterns. In these automatic baud rate modes, the baud rate is measured several times during synchronous data reception, and the result of each measurement is compared with the previous one.

#### ● Automatic baud rate detection mode

Mode0: This mode is for cases starting with 1. In this case, the start bit is measured to 1 (falling edge to rising edge).

Mode1: This pattern is for any character beginning with a 10xx bit pattern. In this case, USART measures the duration of the start bit and the first data bit. Measurements are taken falling edge to falling edge, ensuring better accuracy in the case of slow signal tilt.

Parallel data mode: detection is performed for each intermediate transition of the RX line. If the conversion on the RX is not sufficiently synchronized with the receiver (the receiver calculates the baud rate based on 0 bits), an error will occur.

Note: In automatic baud rate detection mode, if the baud rate clock is close to one frequency division of the fck clock, it will lead to a large error.

### 37.3.9 Multiprocessor communication

It is possible to perform USART multiprocessor communications (with several USARTs connected in a network). For example, a USART device may be the master, and its TX output is connected to the RX input of other USART slave devices; The respective TX output logic of the USART slave devices is coupled together and connected to the RX input of the master device.

In multiprocessor configurations, it is often desirable that only the intended message recipient actively receives the full message contents, thus reducing redundant USART service overhead for all non-addressed receivers. The unaddressed device is configured in silent mode.

The silence function allows non-addressable devices to be placed in silent mode. To use the silent mode feature, the RWU bit must be set in the USART\_CR1 register.

When the Mute mode is enabled:

- Any receive status bits will not be set.
- All reception interrupts are disabled.
- The RWU bit in the USART\_CR1 register is set to 1. RWU can be controlled automatically by hardware or by software under certain conditions.

Depending on the status of the WAKE bit in the USART\_CR1 register, USART can enter or exit the silent mode in two ways.

- If the WAKE bit is set to 0: Idle bus detection is performed.
- If the WAKE bit is set to 1: Address tag detection is performed.

#### 37.3.9.1 Idle bus detection (WAKE=0)

The USART enters mute mode when the RWU bit is written to 1. It wakes up when an Idle frame is detected. RWU can also be written to 0 by software. An example of mute mode behavior using idle line detection is given in the figure below.

Silent mode using idle bus detection

#### 37.3.9.2 address mark detection (WAKE = 1) (4-or 7-bit address detection)

In this mode, bytes are recognized as addresses if their MSB is a '1' else they are considered as data. In one address byte, the address of the target receiver is placed in a 4-bit or 7-bit LSB. This address is compared by the receiver to its own address, which is programmed in the ADD of the USART\_CR2 register. The selection of 7-bit or 4-bit address detection is done using ADDM 7-bit.

The USART enters mute mode when an address character is received which does not match its programmed address. In this case, the RWU bit is set by hardware. The RXNE flag is not set for this address byte and no interrupt nor DMA request is issued as the USART would have entered mute mode. It exits from mute mode when an address character is received which matches the programmed address. Then the RWU bit is cleared, and subsequent bytes are received normally. The RXNE bit is set for the address character since the RWU bit has been cleared. The RWU bit can be written to as 0 or 1 when the receiver buffer contains no data (RXNE=0 in the USART\_SR register). Otherwise, the write attempt is ignored. An example of mute mode behavior using idle line detection is given in the figure below.

Note: In 7-bit and 9-bit data modes, address detection is performed on 6-bit and 8-bit addresses (ADD [5: 0] and ADD [7: 0]), respectively. This address byte does not set the RXNE flag, and no interrupt or DMA request is issued when USART enters silent mode. When FIFO management is enabled, the software should ensure that there is at least one empty spot in the RXFIFO before entering silent mode. When RWU is written to 1, USART also goes into silent mode. In this case, the RWU bit is automatically set as well. USART exits silent mode when an address character matching the programmed address is received. Clear the RWU bit and receive subsequent bytes normally. When the RWU bit has been cleared, the address character can detect the RXNE/RXFNE bit.

### 37.3.10 USART Modbus Correspondence

The USART offers basic support for the implementation of Modbus/RTU and Modbus/ASCII protocols. Modbus/RTU is a half-duplex block transfer protocol. The control parts of the protocol (address identification, block integrity control, and command interpretation) must be implemented in software. USART provides basic support: end block detection, with no software overhead or other resources.

#### Modbus/RTU

In this mode, the end of a block is recognized by "silent" (idle line) for more than 2 characters. This function is realized through a programmable timeout function. The timeout function and interrupt must be activated by the RTOEN bit in the USART\_CR2 register and the RTOIE in the USART\_CR1 register. Timeout values corresponding to 2 character times (e.g. 22 x bit times) must be programmed in the RTO register. When the receive line is idle during this period of time, after the last stop bit is received, an interrupt is generated to inform the software that the current block reception is complete.

#### Modbus/ASCII

In this mode, the end of the block is identified by a specific (CR/LF) character sequence. USART uses the character matching function to manage this mechanism.

Exit the silent mode when the corresponding character is received by writing the corresponding character in the ADD [7: 0] field.

### 37.3.11 Parity control

Parity control (generation of parity bit in transmission and parity checking in reception) can be enabled by setting the PCE bit in the USART\_CR1 register.

**Even check:** The check bit causes 7 or 8 LSB data in a frame and the number of ones in the check bit to be even. For example: data = 00110101, there are 4 ones, if even check is selected (PS = 0 in USART\_CR1), the check bit will be 0.

**Odd check:** This check bit makes 7 or 8 LSB data in a frame and the number of ones in the check bit odd.

For example: data = 00110101, there are 4 ones, if odd check is selected (PS = 1 in USART\_CR1), the check bit will be 1.

Transmission mode: If the PCE bit of USART\_CR1 is set, the MSB bit of the data written into the data register is replaced by the check bit and sent out (if even check even ones, if odd check odd ones are selected. If the parity fails, the PE flag in the USART\_SR register is set to 1, and an interrupt is generated if the PEIE of the USART\_CR1 register is set in advance.

### 37.3.12 LIN Mode

Configure USART\_CR2. LINEN = 1 to select LIN mode. In LIN mode, the following bits must be kept cleared:

1. CLKEN of the USART\_CR2 register;
2. STOP/SCEN/HDSEL/IREN of the USART\_CR3 register.

#### 37.3.12.1 Transmission

Compared with general USART transmission, LIN transmission has the following differences:

M = 0, the data length is 8 bits;

USART\_CR2. LINEN = 1 needs to be configured. After setting SBK, 13 bits of 0 will be transmitted as a disconnected frame.

#### 37.3.12.2 Reception

When the LIN mode is enabled, the open frame detection circuit is activated. The detection is totally independent from the normal USART receiver. The disconnected frame can be detected as soon as it appears, whether when the bus is idle or during the transmission of a data frame, the data frame has not been completed, and the transmission of the disconnected frame is inserted.

When the receiver is activated (RE = 1 for USART\_CR1), the circuit detects a start signal on RX. The method of detecting the start bit is the same as the detection of broken frames or data. When the start bit is detected, the circuit samples each subsequent bit at the 8th, 9th and 10th oversampling clock points of each bit. If 10 (when LBDL of USART\_CR2 = 0) or 11 (when LBDL of USART\_CR2 = 1) consecutive bits are 0, followed by a delimiter, the LBD flag of USART\_SR is set. If the LBDIE bit=1, an interrupt is generated. Before confirming that the frame is broken, check the delimiter because it means that the RX line has returned to high level.

If a '1' is sampled before the 10 or 11 have occurred, the break detection circuit cancels the current detection and searches for a start bit again. If the LIN mode is disabled, the receiver continues to operate as normal USART, and there is no need to consider detecting a broken frame.

If LIN mode is not activated (LINEN = 0), the receiver still operates normally in USART mode and does not perform disconnection detection.

If LIN mode is activated (LINEN = 1), the receiver stops as soon as a frame error occurs (i.e., the stop bit detects '0', which occurs in a broken frame) until the broken frame detection circuit receives either a 1 (this occurs when the broken frame is not completely issued), or a delimiter (this occurs when a complete broken frame has been detected).

### 37.3.13 Synchronous Mode

Select the synchronization mode by writing the CLKEN bit on the USART\_CR2 register

#### 37.3.13.1 Master mode

In synchronous mode, the following bits must be kept cleared:

LINEN bit in the USART\_CR2 register

- SCEN, HDSEL and IREN bits in the USART\_CR3 register

The USART can be used to control bidirectional synchronous serial communications in master mode. The CK pin is the output of the USART transmitter clock. No clock pulses are sent to the CK pin during start bit and stop bit. Depending on the state of the LBCL bit in the USART\_CR2 register, clock pulses are, or are not, generated during the last valid data bit. The CPOL bit in the USART\_CR2 register is used to select the clock polarity, and the CPHA bit in the USART\_CR2 register is used to select the phase of the external clock.

The external CK clock is not activated during bus idle periods, until actual data arrives and when a disconnect frame is transmitted. In synchronous master mode, the USART transmitter operates exactly like in asynchronous mode. However, since CK is synchronized with TX (according to CPOL and CPHA), the data on TX is synchronous.

In synchronous master mode, the USART receiver operates in a different way compared to asynchronous mode. If RE is set to 1, the data are sampled on CK (rising or falling edge, depending on CPOL and CPHA), without any oversampling. A given setup and a hold time must be respected (which depends on the baud rate: 1/16 bit time).

Notes:

1. The CK foot and the TX foot work together. Thus, the clock is provided only if the transmitter is enabled (TE = 1) and data are being transmitted (USART\_TDR data register written). This means that it is not possible to receive synchronous data without transmitting data.
2. LBCL, CPOL and CPHA should be configured when both the transmitter and receiver are disabled; When the transmitter or receiver is enabled, these bits cannot be changed
3. It is recommended to set TE and RE in the same instruction to reduce the setup time and hold time of the receiver.
4. USART only supports the main mode: it cannot receive or send data with the input clock from other devices (CK is always the output).

Figure 37-10 USART Data Clock Timing Example (M = 0)

Figure 37-11 RX Data Sample/Hold Time (M = 1)

### 37.3.14 Single-wire Half-duplex communications

The single-wire half-duplex mode is selected by setting the HDSEL bit in the USART\_CR3 register. In this mode, the following bits must be kept cleared:

- LINEN and CLKEN bits of the USART\_CR2 register
- SCEN and IREN bits of the USART\_CR3 register

The USART can be configured to follow a Single-wire Half-duplex protocol. In single-wire half-duplex mode, the TX and RX pins are connected internally. Half-duplex and full-duplex communication are selected using the HDSEL bit in USART\_CR3.

#### When HDSEL is "1":

- RX No longer in use
- When there is no data transmission, TX is always released. Therefore, it behaves as a standard I/O port when idle or received. This means that the I/O must be configured as an open drain when it is not driven by USART.

Apart from this, the communication protocol is similar to normal USART mode. Conflicts on the line are managed by software (e.g. through the use of a central arbiter). In particular, the transmission is never blocked by hardware. The transmission is never blocked by hardware and continues as soon as data are written in the data register while the TE bit is set.

### 37.3.15 USART receive timeout

The receiver timeout feature is enabled by setting the RTOEN bit in the USART\_CR2 control register.

The timeout is set using the RTO bit field in the USART\_RTOR register.

When the set timeout time is exceeded, the USART\_SR register is set to 1. If the RTOIE of CR1 is set, the corresponding interrupt will be generated.

### 37.3.16 Smartcard

Smartcard mode is selected by setting the SCEN bit in the USART\_CR3 register. In Smartcard mode, the following bits must be kept cleared:

- LINEN bit of USART\_CR2 register
- HDSEL and IREN bits of the USART\_CR3 register

Moreover, the CLKEN bit may be set in order to provide a clock to the smartcard.

The Smartcard interface is designed to support asynchronous protocol Smartcards as defined in the ISO 7816-3 standard. T = 0 (character mode) and T = 1 (block mode) are both supported.

### 37.3.16.1 T = 0 (character mode)

The USART should be configured as:

- 8-bit data bit plus check bit: At this time, M = 1 and PCE = 1 in the USART\_CR1 register
- 1.5 STOP bits when sending and receiving: that is, STOP = 11 of the USART\_CR2 register

Note: It is also possible to choose 0.5 stop bit for receiving but it is recommended to use 1.5 stop bits for both transmitting and receiving to avoid switching between the two configurations.

In T = 0 (character) mode, a parity error is indicated at the end of each character during the guard period.

Figure below shows examples of what can be seen on the data line with and without parity error.

Figure 37-12 ISO7816-3 asynchronous protocol

When connected to a smartcard, the USART TX output drives a bidirectional line that is also driven by the smartcard. In order to do this, SW\_RX must be connected to the same I/O port as TX. The output enable bit TX\_EN of the transmitter is set during the transmission of the start bit and the data byte, and is released during the transmission of the stop bit (weak pull-up), so the receiver can pull the data line low in the event that a check error is found. If TX\_EN is not used, TX is pulled high during the stop bit: in this case, the receiver can drive this line as long as TX is configured as an open drain.

Smartcard is a single wire half duplex communication protocol.

- Data is sent out from the send shift register and is delayed by a minimum of 1/2 baud clock. In normal operation a full transmit shift register will start shifting on the next baud clock edge. In Smartcard mode this transmission is further delayed by a guaranteed 1/2 baud clock.
- If a parity error is detected during reception of a data frame set to 0.5 or 1.5 stop bits, the transmit line is pulled down one clock cycle after the reception of the frame is completed (i.e., at the end of the stop bits). This is to indicate to the Smartcard that the data transmitted to USART has not been correctly received. This NACK signal (pulling down the transmit line by one clock cycle) will produce a frame error at the transmit end (the transmit end is configured with 1.5 stop bits). The application may handle the retransmission data according to the protocol. A parity error is 'NACK'ed by the receiver if the NACK control bit is set, otherwise a NACK is not transmitted. The TXE bit (TXFNF bit when FIFO mode is enabled) can be set using the TXFRQ bit in the register. If the received character is wrong, the RXNE (RXFNE when FIFO mode is enabled)/receive DMA request is not activated.
- Automatic retry in smart card transmission: A delay of 2.5 clock cycles is inserted between the USART detection NACK and the start bit of the repeated character. The TC bit is set immediately

after the last repeated character is received (unprotected time). If the software wants to repeat it again, it must ensure the minimum 2 clock cycles required by the standard.

- In transmission, USART inserts a guard time (as per the guard time register) between two consecutive characters. Since the guard time is measured after the stop bit of the previous character, the GT [7: 0] register must be programmed to the required CGT (character guard time, defined by the 7816-3 specification) minus 12 (the duration of one character).
- The setting of the TC flag can be delayed by programming the guard time register. In normal operation, TC is asserted when the transmit shift register is empty and no further transmit requests are outstanding. In smart card mode, an empty transmit shift register will trigger the guard time counter to start counting up, and TC is forced down during this time. When the guard time counter reaches the value in the guard time register, TC is set high.
- The revocation of the TC flag is not affected by the smart card mode.
- If the transmitter detects a frame error (receiving a NACK signal from the receiver), the receiving function module of the transmitter does not detect the NACK as the start bit. According to the ISO protocol, the duration of the received NACK may be 1 or 2 clock cycles.
- On the receiver side, if a check error is detected and a NACK is transmitted, the receiver does not detect the NACK as the start bit.

Note:

1. The disconnect frame does not make sense in smart card mode. A 0x00 data with a frame error will be treated as data rather than a broken frame.
2. When switching TE bits back and forth, no IDLE frame is transmitted. The IDLE frame is not defined by the ISO protocol.

Figure below details how the NACK signal is sampled by the USART. In this example, the USART transmits a data and is configured with 1.5 stop bits. The receiver part of the USART is enabled in order to check the integrity of the data and the NACK signal.

Figure 37-13 1.5 stop bit detection of parity error

The USART can provide a clock to the Smartcard through the CK output. In Smartcard mode, CK is not associated to the communication but is simply derived from the internal peripheral input clock through a 5-bit prescaler. The division ratio is configured in the prescaler register USART\_GTPR. The CK frequency can be programmed from  $f_{CK}/2$  to  $f_{CK}/62$ , where  $f_{CK}$  is the peripheral input clock.

**37.3.16.2 T = 1 (block mode)**

In block mode, the software must program the RTOR register to a BWT (Block Wait Time)-11 value when making a read request to the smart card. If no reply is received from the card before the expiration of this period, a timeout interrupt is generated. An RXNE/RXFNE interrupt is signaled if the first character is received before the expiration of the period.

NOTE: The RXNE/RXFNE interrupt must be enabled even when reading from the smart card in block mode using USART in DMA mode. At the same time, DMA must only be enabled after the first byte is received.

In a smart card protocol definition, the BWT/CWT value should be defined from the beginning of the last character (start bit). Given the length of the last character itself, the RTO register must be programmed as BWT-11 or CWT-11, respectively.

The block length counter is used to count all characters received by USART. When USART sends, this counter is reset. The length of the block is communicated by the smart card in the third byte (preamble byte) of the block. This value must be programmed into the BLEN field of the USART\_RTOR register. When using DMA mode, this register field must be programmed to a minimum value before the block starts. According to this value, an interrupt is generated after the 4th character received. The software must read the LEN field (third byte) and its value must be read from the receive buffer.

In interrupt-driven receive mode, the length of the block can be checked by software or by programming the BLEN value. However, the maximum value of BLEN (0xFF) can be programmed before the start of the block. The true value is programmed after receiving the third character.

If the block uses the LRC longitudinal redundancy check (coda byte), then BLEN = LEN. If the block uses the CRC mechanism (2 bytes), then BLEN = LEN+1 must be programmed. The total block length (including preamble, epilogue, and information bytes) is equal to BLEN+4. The end of the block is signaled to the software via an EOBFF flag and an interrupt (when the EOBI bit is set).

**37.3.17 IrDA SIR ENDEC Functional module**

IrDA mode is selected by setting the IREN bit in the USART\_CR3 register. In IrDA mode, the following bits must be kept cleared:

- LINEN, STOP and CLKEN bits of the USART\_CR2 register
- The SCEN and HDSEL bits of the USART\_CR3 register.

**37.3.17.1 IrDA normal mode**

The IrDA SIR physical layer specifies the use of an inverted return-to-zero modulation scheme (RZI), which uses an infrared light pulse to represent a logic '0' (see figure below). The SIR transmit encoder modulates the NRZ (non-return-to-zero) bitstream output from the USART. The output pulse stream is transmitted to an external output driver and infrared LED. USART is SIR ENDEC only supports up to 115.2 Kbps speeds. In normal mode the transmitted pulse width is specified as 3/16 of a bit period.

The SIR receive decoder demodulates the return-to-zero bit stream from the infrared detector and outputs the received NRZ serial bit stream to USART. In the idle state, the decoder input is typically high (flag state). The transmit encoder output has the opposite polarity to the decoder input. A start bit is detected when the decoder input is low.

- IrDA is a half-duplex communication protocol. If the transmitter is busy (i.e. USART is sending data to the IrDA encoder), any data on the IrDA receive line will be ignored by the IrDA decoder. If the receiver is busy (i.e. the USART is receiving decoded data from the IrDA decoder), the data on the TX from the USART to the IrDA will not be encoded by the IrDA. While receiving data, transmission should be avoided as the data to be transmitted could be corrupted.
- The SIR transmit logic transmits '0' as high and '1' as low. The width of the pulse is specified as 3/16th of the selected bit period in normal mode.
- The SIR receive logic interprets the high state as '1' and the low pulse as '0'.
- The output of the transmit encoder has opposite polarity to the input of the decoder. The SIR output is in low state when idle.
- The SIR decoder converts the IrDA-compliant received signal into a bitstream for the USART.
- The IrDA specification requires pulses to be wider than 1.41  $\mu$ s. The acceptable pulse width is programmable. The pulse detection logic on the receiver side filters out pulses having a width of less than 2 PSC cycles (PSC is a prescaled value programmed in the IrDA low power baud rate register USART\_GTPR). Pulses of width less than 1 PSC period are always rejected, but those of width greater than one and less than two periods may be accepted or rejected, those greater than 2 periods will be accepted as a pulse. The IrDA encoder/decoder doesn't work when PSC=0.
- The receiver may communicate with a low power transmitter.
- In IrDA mode, the STOP bit on the USART\_CR2 register must be configured as a STOP bit.

### 37.3.17.2 IrDA low-power mode

#### Transmitter:

In low-power mode the pulse width is not maintained at 3/16 of the bit period. Instead, the width of the pulse is 3 times the low-power baud rate which can be a minimum of 1.42 MHz. Usually this value is 1.8432 MHz ( $1.42 \text{ MHz} < \text{PSC} < 2.12 \text{ MHz}$ ). A low-power mode programmable divisor divides the system clock to achieve this value.

#### Receiver:

Receiving in low-power mode is similar to receiving in normal mode. In order to filter out spike interference pulses, USART should filter out pulses with a width of less than 1 PSC. Only a low level signal of an IrDA low power baud rate clock (PSC in USART\_GTPR) with a duration greater than 2 cycles is accepted as a valid signal.

#### Notes:

1. Pulses having a width of less than 2 and greater than 1 PSC cycle may or may not be filtered out.
2. The setup time of the receiver should be managed by the software. The IrDA physical layer specification specifies a minimum delay of 10 ms between transmission and reception (IrDA is a half-duplex protocol).

Figure 37-14 IrDA SIR ENDEC block diagram

Figure 37-15 IrDA Data Modulation (3/16)-Normal Mode

### 37.3.18 Continuous Communication Using DMA

The USART is capable of performing continuous communications using the DMA. DMA requests for the RX buffer and the TX buffer are generated separately.

Note: In the USART2\_SR register, the TXE/RXNE flag can be cleared to achieve continuous communication.

#### Send with DMA:

DMA mode can be enabled for transmission by setting DMAT bit in the USART\_CR3 register. When the TXE bit is set to '1', the DMA transfers data from the designated SRAM area to the USART\_DR register.

1. Write the USART\_DR register address in the DMA control register to configure it as the destination of the transfer. Data is also moved from memory to this address after each TXE (if FIFO mode TXFNF is enabled)
2. Write the memory address in the DMA control register to configure it as the transfer source. After each TXE (or TXFNF, if FIFO mode is enabled) event, data is loaded from this memory area into the USART\_DR register
3. Configure the total number of bytes to be transferred to the DMA control register.
4. Configure the channel priority in the DMA register
5. Depending on the requirements of the application, the configuration generates a DMA interrupt when the transfer is half or all complete.
6. Activate the channel on the DMA register.

When the number of data transfers programmed in the DMA Controller is reached, the DMA controller generates an interrupt on the DMA channel interrupt vector. Detecting the TC flag of the USART\_SR register can confirm whether the USART communication has ended, which can avoid corruption of the last transmitted data before turning off USART or entering the shutdown mode; The software needs to wait for TXE = 1 first and then for TC = 1.

### Receiving with DMA:

Reception using DMA can be activated by setting the DMAR bit of the USART\_CR3 register. Each time one byte is received, the DMA controller transfers data from the USART\_DR register to the designated SRAM area (refer to DMA related description). The steps to assign a DMA channel for USART reception are as follows (x represents the channel number):

1. Configure the USART\_DR register address as the source address of the transfer through the DMA control register. The data will be moved from this address to the memory after each RXNE event.
2. Configure the memory address as the destination address of the transfer through the DMA control register. After each RXNE event, data is transferred from USART\_DR to this memory.
3. Configure the total number of bytes to be transferred in the DMA control register.
4. Configure the channel priority on the DMA register.
5. According to the requirements of the application, configure whether the DMA interrupt is generated when the transmission is half or all completed.
6. Activate this channel on the DMA control register.

When the number of data transfers programmed in the DMA Controller is reached, the DMA controller generates an interrupt on the DMA channel interrupt vector.

Figure 37-16 transmitted using DMA

Figure 37-17 Using DMA Receiving

### Error flags and interrupt generation in multi-buffer communication

In the case of multi-buffer communication, if any error occurs during the communication, an error flag will be set after the current byte is transmitted.

An interrupt will be generated if the interrupt enable flag is set. For framing error, overrun error and noise flag which are asserted with RXNE incase of single byte reception, there will be separate error flag interrupt enable bit, which if set will issue an interrupt after the current byte with either of these errors.

### 37.3.19 Hardware flow control

#### 37.3.19.1 RS232 hardware flow control

It is possible to control the serial data flow between 2 devices by using the nCTS input and the nRTS output. The figure below shows how to connect two devices in this mode.

Figure 37-18 Hardware flow control between two USARTs

By setting RTSE and CTSE in USART\_CR3, RTS and CTS flow control can be enabled independently, respectively.

**RTS Flow Control:**

If the RTS flow control is enabled (RTSE=1), then nRTS is asserted (tied low) as long as the USART receiver is ready to receive a new data. When the receive register is full, nRTS is deasserted, indicating that the transmission is expected to stop at the end of the current frame. The following diagram is an example of a communication with RTS flow control enabled.

Figure 37-19 RTS flow control

**CTS Flow Control:**

If the CTS flow control is enabled (CTSE=1), then the transmitter checks the nCTS input before transmitting the next frame. If nCTS is valid (pulled low), the next data is transmitted (assuming that data is ready for transmission, i.e. TXE = 0), otherwise the next frame of data is not transmitted. When CTS is deasserted during a transmission, the current transmission is completed before the transmitter stops. When CTSE = 1, the CTSIF status bit is automatically set by hardware as soon as the nCTS input toggles. It indicates when the receiver becomes ready or not ready for communication. An interrupt is generated if the CTSIE bit in the USART\_CR3 register is set. The following diagram is an example of enabling CTS flow control communication.

Figure 37-20 CTS flow control

### 37.3.19.2 RS485 hardware flow control

Enabled by setting the bit DEM in the USART\_CR3 control register, the user is able to activate external transceiver control through the DE (drive enable) signal. The assertion time is the time when the DE signal is activated to the start of the start bit. It is programmed using the DEAT [4: 0] bit field in the USART\_CR1 control register. The deactivation time is the time from the end of the last stop bit in the transmission data to the deactivation of the DE signal. It is programmed using the DEDT [4: 0] bit field in the USART\_CR1 control register. The polarity of the DE signal can be configured using the DEP bit in the USART\_CR3 control register.

In USART, DEAT and DEDT are expressed in sampling time units (1/8 or 1/16 bit time, depending on the oversampling rate).

### 37.3.20 Interrupt requests

Table 37-5 USART interrupt requests

| Interrupt vector | Flag bit  | Enable Control bit |
|------------------|-----------|--------------------|
| usart            | txe       | txeie              |
|                  | cts       | ctsie              |
|                  | tc        | tcie               |
|                  | rxne      | rxneie             |

RTOR can be written dynamically. If the new value is less than or equal to the counter, the RTOF flag is set.

## 38. Universal Asynchronous Receivers/Transmitter (UART)

### 38.1 Introduction

UART is a programmable universal asynchronous transceiver.

### 38.2 Main Features

- AMBA APB interface
- Support 5/6/7/8/9-bit serial data
- Supports 1/2 stop bits (for 5-bit data: 1/1.5 stop bits)
- Support sending address/data
- Support fixed parity check
- Supports disconnected frames
- Detect start bit errors
- Support programmable fractional baud rates
- Support SWAP function
- Support MSB FIRST endianness switching
- Support DMA transmission
- Support 4-bit fractional baud

### 38.3 UART functional description

#### 38.3.1 UART (RS232) serial protocol

Because the serial communication between the UART and the selected device is asynchronous, additional bits (start and stop) are added to the serial data to indicate the start and end. These bits can be used to synchronize the two devices. This serial data structure consisting of start bits and stop bits is called a character, as shown in the following figure.

Figure 38-1 serial data format

An additional parity bit can be added to the serial character. This bit occurs after the last data bit in the character structure and before the stop bit in order to provide the UART with the ability to perform error checking on the received data.

The UART Line Control Register ("CR1" section in the Register Description) is used to control the serial character characteristics. The individual bits of the data word are transmitted after the start bit, starting with the least significant bit (LSB). They are followed by an optional parity bit followed by a stop bit, which can be 1, 1.5, or 2.

Note: The stop bit duration for UART implementations may be longer for the following reasons:

- Idle time inserted between some configured characters

All bits in the transmission are transmitted for exactly the same duration; The exception to this is the half stop bit when 1.5 stop bits are used. This duration is referred to as a bit period or bit time; One bit of time is equal to sixteen baud clocks.

To ensure line stability, once the start bit is detected, the receiver samples the serial input data at approximately the midpoint of the bit time.

Figure 38-2 receiver serial data sampling points

As part of the 16550 standard, an optional baud clock reference output signal provides timing information for receiving devices that require it. The baud rate of the UART is controlled by a serial clock `sclk` or `pclk` in a single-clock implementation and a frequency division latch register (BRR).

The following figure shows the timing diagram of the `baudout_n` output for different divisor values.

Figure 38-3 timing diagram

### 38.3.2 9-bit data transfer

The UART may be configured to have 9-bit data transmission in both transmit and receive modes. The 9th bit in the character occurs after the 8th bit of the character and before the parity bit. The figure below shows the serial transfer of characters, where D8 denotes the 9th bit, and also shows the general serial transfer in 9-bit mode. (This is the normal little-endian mode. If it is the big-endian mode, the order of 9 data bits will be switched)

Figure 38-4 9 Bit data transmission

By enabling 9-bit data transfer mode, UART can be used in multipoint systems where one master device is connected to multiple slave devices in the system. The master communicates with one of the

slaves. When the master device wants to transfer a block of data to a slave device, it first sends an address byte to identify the target slave device.

The distinction between address/data bytes is done based on the 9th bit in the input character. If the 9th bit is set to 0, the character represents a data byte. If the 9th bit is set to 1, the character represents the address byte. All slave systems compare the address bytes to their own addresses, and only the target slave system (where the addresses match) is able to receive data from the master system. The master starts sending data bytes to the target slave. The unaddressed slave system ignores incoming data until a new address byte is received.

Note an address followed by 2 data bytes. The address byte is output with the 9th bit (D8) set to 1, while the data byte is emitted with the 9th bit (D8) set to 0. The parity bit is an optional field.

The configuration of the UART for 9-bit data transmission does the following:

- The CR3 [0] bit is used to enable or disable 9-bit data transfer.
- In the case of reception, the CR1 [1] bit is used to select between hardware and software based address matching.
- The CR3 [2] bit is used to enable the transmit address in the case of transmission.
- The CR3 [3] bit is used to select between hardware and software based address transfer.
- The TAR and RAR registers are used to send the address and match the received address, respectively.
- The TDR and RDR registers are 9-bit registers for data transfer in 9-bit mode.
- The SR [8] bit is used to indicate an address reception interrupt.

### Send Mode

UART supports two types of transmission modes:

- Transmission Mode 0 (when (CR3 [3]) is set to 0)
- Transmission Mode 1 (when (CR3 [3]) is set to 1)

### Transmission Mode 0

In transfer mode 0, addresses are programmed in the transfer address register (TAR) and data is written to the transfer hold register (TDR). The 9th bit of the TDR register is not applicable in this mode. The figure below shows address and data transmission based on SEND\_ADDR(CR3 [2]), TDR NULL conditions.

Figure 38-5 Automatic address transfer flow chart

The address of the destination slave to which data is to be transferred is programmed in the TAR register. The SEND\_ADDR(CR3 [2]) bit must be enabled to transfer the destination slave address in the TAR register on the serial UART line, where the 9th data bit is set to 1, indicating that the address is being sent to the slave. UART clears the SEND\_ADDR bit after the address character begins to be transmitted on the UART line.

The data needed to be transferred to the target slave is programmed through a transfer hold register (TDR). Data is transmitted on the UART line, and the 9th data bit is set to 0, indicating that data is being sent to the slave.

### Transmission Mode 1

In Transfer Mode 1, the TDR register is 9 bits wide and both addresses and data are programmed through the TDR register. UART does not distinguish between address and data. The SEND\_ADDR(CR3 [2]) bit and the Transfer Address Register (TAR) are not applicable for this mode. Depending on whether address/data must be sent, the software must write the 9th bit with 1/0.

Table 38-1 Transfer Relationship Table

| M_E | TX_MODE | SEND_ADDR | Usage scenarios             |
|-----|---------|-----------|-----------------------------|
| 0   | X       | X         | Send 8-bit TDR data         |
| 1   | 0       | 0         | Send "0 +8-bit TDR data"    |
| 1   | 0       | 1         | Send "1 +8-bit TAR address" |
| 1   | 1       | X         | Send "9-bit TDR data"       |

Note: This table describes several sending scenarios and corresponding configurations that can be used as a sender.

### Receiving Mode

UART supports two reception modes:

- Hardware address match receive mode (when ADDR\_Match(CR3 [1]) is set to 1)
- Software Address Match Receive Mode (when ADDR\_Match(CR3 [1]) is set to 0)

#### Hardware address matching receiving mode

In hardware address matching receive mode, if the 9th bit of the receive character is set to 1, the UART matches the receive character to the address programmed in the receive address register (RAR):

If the received address successfully matches the programmed address in the RAR register, the data byte is then received.

If the address match fails, the UART controller discards the data characters until a matching address is received.

The following figure shows the data byte receiving flow chart based on the address matching function.

Figure38-6 Data byte receiving flow chart of address matching function

The UART receives characters regardless of whether the 9th bit of data is set to 1. If the 9th bit of the received character is set to 1, it clears the internal address match flag and then compares the received 8-bit character information with the address programmed in the RAR register.

If the received address characters successfully matches the address programmed in the RAR register, the address match flag is set to 1 and the received character is pushed to the RDR register, and the ADDR\_RCVD bit in the SR register is set to indicate that the address has been received, and the subsequent data byte (the 9th bit of the received character is set to 0) is pushed to the RDR.

If the address fails to match the RAR register and a frame error is found in the parity or received address character, the received address string is still pushed to the RDR register, and the ADDR\_RCVD and PE/FE error bits are set to 1.

If any interrupt character is received, UART treats it as a special character and pushes it to the RDR register regardless of the address match flag.

#### Software address matching receiving mode

In this mode of operation, the UART does not perform address matching to the received address character of the RAR register (the 9th bit of data is set to 1). The UART always receives 9 bits of data, advancing the RDR register. Whenever an address byte is received and indicated by the ADDR\_RCVD bit in the line status register, the address must be compared by the user himself.

### 38.3.3 Baud rate

The baud rate of the UART is controlled by pclk and the divided latch register (BRR) and the fractional baud rate register BRRF.

The baud rate is determined by:

- Serial clock operating frequency (pclk)

- Baud rate generator divisor (consists of BRR register)
- Acceptable baud rate error

The equation for calculating the baud rate is as follows:

$$\text{Baud rate} = \text{serial clock operating frequency} / (16 * \text{DIVISOR}) \quad (1)$$

Where, DIVISOR-the number (hex) used to program the BRR.

Serial Clock Frequency-The frequency at the UART pclk pin.

According to equation (1), DIVISOR can be calculated as:  $\text{DIVISOR} = \text{serial clock frequency} / (16 * \text{baud rate})$

(The fractional part calculated by the equation is placed in BRRF)

Also from Equation (1), it can also be shown that  $\text{serial clock frequency} = \text{baud rate} * 16 * \text{divisor}$

The error between the baud rate and the selected baud rate calibration is as follows:

$$\text{Percentage error} = (|\text{baud rate} - \text{selected baud rate}|) / \text{baud rate} * 100\%$$

Table 38-2 Error calculation when setting baud rate

| Baud rate |       | fpclk = 4 MHZ |                                            |            | fpclk = 24 MHZ |                                            |            | fpclk = 48 MHZ |                                            |            |
|-----------|-------|---------------|--------------------------------------------|------------|----------------|--------------------------------------------|------------|----------------|--------------------------------------------|------------|
| No.       | kbps  | Actual        | Value programmed in the baud rate register | Error%     | Actual         | Value programmed in the baud rate register | Error%     | Actual         | Value programmed in the baud rate register | Error%     |

| 10        | 4500  | Impossible    | Impossible                                 | Impossible | Impossible     | Impossible                                 | Impossible | Impossible     | Impossible                                 | Impossible |

Notes:

1. The lower the clock frequency of the CPU, the lower the error at a particular baud rate. The upper limit of the achievable baud rate can be fixed with this data.
2. When configuring the clock, because the baud rate clock is divided on the system clock, there will be an error between the obtained clock frequency and the actual clock frequency. The configured clock error needs to be within 2% to work properly.

#### 38.3.4 The UART receiver tolerates changes in the clock

The UART asynchronous receiver operates correctly only if the total clock system deviation is less than the tolerance of the UART receiver. The causes which contribute to the total deviation are:

- DTRA: deviation due to the transmitter error (which also includes the deviation of the transmitter's local oscillator)
- DQUANT: error due to the baud rate quantization of the receiver
- DREC: deviation of the receiver local oscillator
- DTCL: deviation due to the transmission line (generally due to the transceivers which can introduce an asymmetry between the low-to-high transition timing and the high-to-low transition timing).

Need to meet:  $\text{DTRA} + \text{DQUANT} + \text{DREC} + \text{DTCL} < \text{tolerance of UART receiver}$

Table 38-3 UART receiver tolerance when DIV\_Fraction is 0

| M bit | NF is an error |        | NF doesn't care |        |
|-------|----------------|--------|-----------------|--------|
| 5     | 5.66%          | -5.71% | 6.67%           | -6.74% |
| 6     | 4.92%          | -4.96% | 5.66%           | 5.71%  |
| 7     | 4.35%          | -4.38% | 4.92%           | 4.96%  |
| 8     | 3.59%          | -5.85% | 3.90%           | -5.91% |

Table 38-4 UART receiver tolerance when DIV\_Fraction is not 0

| M bit | NF is an error |        | NF doesn't care |        |
|-------|----------------|--------|-----------------|--------|
| 5     | 4.72%          | -4.76% | 5.56%           | -5.62% |
| 6     | 4.92%          | -4.13% | 4.72%           | -4.76% |
| 7     | 4.35%          | -3.65% | 4.10%           | -4.13% |
| 8     | 4.53%          | -5.2%  | 4.58%           | -5.31% |

### 38.3.5 Continuous Communication Using DMA

The UART may utilize DMA continuous communication. DMA requests for the Rx buffer and the Tx buffer are generated separately.

#### Transmission using DMA

Transmission with DMA is enabled by configuring UART\_CR3.DMAT. When the send data register is empty, the DMA transfers data from the designated SRAM area to the UART\_DR register.

The configuration steps of DMA transmission are as follows:

- Configure the UART\_TDR register address as the destination address for the DMA transfer. After each send data register empty event, data will be transferred to this address;
- Configure a memory (e.g. SRAM) address as the source address for DMA transfers. Loading read data from this memory into the UART\_TDR register after each transmit data register empty event;
- Write the DMA control register to configure the number of transferred bytes;
- Write the DMA register to configure channel priority;
- Enable a DMA channel;

When the transmission reaches the configured number of transmission bytes, the DMA controller generates an interrupt request.

#### Reception using DMA

Utilizing DMA reception is enabled by configuring UART\_CR3.DMAR. For each byte received, the DMA transfers data from the UART\_DR register to the designated SRAM area.

The configuration steps of DMA reception are as follows:

- Configure the UART\_RDR register address as the source address for the DMA transfer. After each received data register non-empty event, data is transferred to memory by reading data from this UART\_RDR register address;
- Configure the SRAM memory address as the destination address for the DMA transfer. After each reception of a data register non-empty event, data will be transferred from the UART\_RDR register to this address;
- Write the DMA control register to configure the number of transferred bytes;
- Write the DMA register to configure channel priority;
- Enable a DMA channel;

When the transmission reaches the configured number of transmission bytes, the DMA controller generates an interrupt request.

### 38.3.6 Interrupts and events

Assertion of UART Interrupt Output Signal (intr)-An interrupt occurs as soon as one of several preferential interrupt types is enabled and activated.

When an interrupt occurs, the host may access the IIDR register to determine the interrupt type.

The following interrupt types can be enabled via the CR2 register:

- Receiver error
- Receiver data available
- Send hold register empty (in programmable TDR interrupt mode)
- Busy detection indication

Figure 38-7 USART interrupt mapping diagram

These interrupt types are detailed in the table below.

Table 38-5 interrupt control function

| Interrupt ID |       |       |       | Interrupt Set and Reset Functions |                                 |                                                                                      |                                        |
|--------------|-------|-------|-------|-----------------------------------|---------------------------------|--------------------------------------------------------------------------------------|----------------------------------------|

## 38.4 TIMx registers

The peripheral registers have to be accessed by half-words (16 bits) or words (32 bits).

Terms: set = set to 1; Clear = Clear is 0;

### 38.4.1 UART DR, Address = 0X00 (DR)

Address offset: 0x00

Reset value: 0x0000 0000

|    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |    |

| 6 | TXE       | R     | 1'b1 | Send is empty.<br>This bit is set whenever no data is currently being sent and the TDR is empty.<br>0: Send is not empty<br>1: Send is empty                                                                                                                                                                                                                                                                                                                                                                                                         |
| 5 | TDRE      | R     | 1'b1 | Send keeps register empty.<br>This bit indicates that the TDR is null. This bit is set whenever data is transferred from the TDR to the transmitter shift register and no new data is written to the TDR. This also causes a TDR interrupt to occur if it is enabled.<br>0: TDR non-empty<br>1: TDR is empty                                                                                                                                                                                                                                         |
| 4 | BRI       | RC_W1 | 1'b0 | The break interrupt bit.<br>This is used to indicate that an interrupt sequence is detected on the serial input data. If in UART mode, it is set whenever the serial input sin remains in a logic "0" state for longer than the sum of the start time + data bits + parity bits + stop bits.<br>0: No break sequence detected<br>1: break sequence detected<br>Write 1 to clear this bit                                                                                                                                                             |
| 3 | FE        | RC_W1 | 1'b0 | Frame error bit.<br>This is used to indicate that a frame error has occurred in the receiver. A frame error occurs when the receiver does not detect a valid STOP bit in the received data. It should be noted that if a break occurs, the frame error bit will also be set, as shown by the break interrupt bit. This happens because the break character implicitly generates a frame error by holding the sin input to a logical 0 longer than the duration of the character.<br>0: No frame error<br>1: Frame error<br>Write 1 to clear this bit |
| 2 | PE        | RC_W1 | 1'b0 | Parity error bit.<br>If a parity enable bit is set, this is used to indicate the occurrence of a parity error in the receiver. It should be noted that if a break occurs, in which case PE is also set if parity generation and detection is enabled and parity is set to odd.<br>0: No parity error<br>1: Parity error<br>Write 1 to clear this bit                                                                                                                                                                                                 |
| 1 | ORE       | RC_W1 | 1'b0 | Overflow error bit.<br>This is used to indicate the occurrence of an overflow error. This happens if a new data character is received before the previous data is read. The ORE bit is set when a new character reaches the receiver before the previous character is read from the RDR. When this happens, the data in the RDR is overwritten.<br>0: No overflow error<br>1: Overflow error<br>Write 1 to clear this bit                                                                                                                            |
| 0 | RXNE      | R     | 1'b0 | Data ready bit.<br>This is used to indicate that the receiver includes at least one character in the RDR. This bit is cleared when the RDR is read.<br>0: Data not ready<br>1: Data ready                                                                                                                                                                                                                                                                                                                                                            |

| 5      | SP       | RW  | 1'b0        | Fixed parity.<br>Writable only if UART is not busy. This bit is used to force a fixed parity value. When PCE, PS, and SP are set to 1, a parity bit is sent and checked for logical 0. If PCE and Stick Parity are set to 1, and PS is a logical 0, a parity bit is sent and checked for logical 1. If this bit is set to 0, then fixed parity is disabled.<br>0: Fixed parity disabled<br>1: Fixed parity enabled                                                                                                                                                                                                                                                                                                  |
| 4      | PS       | RW  | 1'b0        | Even parity selection.<br>Writable only if UART is not busy. When parity is enabled, this is used to select between even and odd parity. If set to 1, an even number of logical "1s" is transmitted or checked. If set to zero, an odd number of logical "ones" is transmitted or checked.<br>0: odd parity<br>1: Even parity                                                                                                                                                                                                                                                                                                                                                                                       |
| 3      | PCE      | RW  | 1'b0        | Parity enabled.<br>Writable only if UART is not busy. This bit is used to enable and disable parity generation and detection in transmitted and received serial characters, respectively.<br>0: Disable parity<br>1: Enable parity                                                                                                                                                                                                                                                                                                                                                                                                                                                                                  |
| 2      | STOP     | RW  | 1'b0        | Number of Stop bits.<br>Writable only if UART is not busy. This is used to select the number of stop bits for each character that the peripheral device will send and receive. If set to zero, 1 stop bit is transferred in the serial data. If set to 1 and the data bit is set to 5, 1.5 stop bits are sent. Otherwise, 2 stop bits are transmitted. Note that regardless of the number of stop bits selected, the receiver will only check the first Stop bit. Note: The STOP bit duration of UART implementations may be longer due to the idle time inserted between characters and the baud clock divisor value in the transmission direction for some configurations;<br>0: 1 stop bit<br>1: 1.5/2 stop bits |
| 1: 0   | M        | RW  | 2'b0        | Data length selection.<br>Writable only if UART is not busy. When M_E in CR3 is set to 0, this register is used to select the number of data bits for each character that the peripheral device will send and receive.                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |

| 3 | TX_MODE    | RW | 1'b0 | Transfer mode control bit. This bit is used to control the type of transmission mode during the 9-bit data transmission.<br>1: In this mode of operation, the transfer hold register is 9 bits wide. The user needs to ensure that the address/data of the TDR register is written correctly.<br>Address: 9th digit set to 1<br>Data: 9th digit set to 0<br>Note: The Transfer Address Register (TAR) is not suitable for this mode of operation.<br>0: In this mode of operation, the width of the transfer hold register is 8 bits. The user needs to program the address into the transfer address register and the data into the TDR register. The SEND_ADDR bit serves as a control knob indicating when the UART transmits an address. |
| 2 | SEND_ADDR  | RW | 1'b0 | Send the address control bit.<br>This bit serves as a control knob for the user to determine when to send an address in transmission mode.<br>Note: 1. After the address character is issued, this bit is automatically cleared by the hardware. Users should not program this bit to 0.<br>2. This field is only applicable if the M_E bit is set to 1 and TX_MODE is set to 0.<br>0: 9-bit character content from TDR register<br>1: 9-bit character content: The 9th bit is set to 1 and the remaining 8 bits will match what is being programmed in the "Transfer Address Register".                                                                                                                                                     |
| 1 | ADDR_MATCH | RW | 1'b0 | Address matching pattern.<br>This bit is used to enable address matching during reception.<br>In address match mode, UART will wait for an incoming character with the 9th bit set to 1. And further check whether the address matches the address programmed in the "Receive Address Match Register". If there is a match, the subsequent characters are considered valid data and UART starts receiving data.<br>In normal mode, the UART will start receiving data and 9-bit characters will form. The user is responsible for reading data and distinguishing between b/n addresses and data.<br>Note: This field applies only if M_E is set to 1. Value:<br>0: normal mode<br>1: Address matching mode                                  |
| 0 | M_E        | RW | 1'b0 | Enable 9bit<br>This bit is used to enable the 9-bit data used to send and receive transmissions                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                              |

## 39. Low-power universal asynchronous receivers/transmitters (LPUART)

The LPUART is an UART which allows bidirectional UART communications with a limited power consumption. Only a 32.768 kHz LSE clock allows for UART communication up to 9600 baud/s. Higher baud rates can be reached when the LPUART is clocked by clock sources different from the LSE clock.

Even when the microcontroller is in low-power mode, the LPUART can wait for an incoming UART frame while having an extremely low energy consumption. The LPUART includes all necessary hardware support to make asynchronous serial communications possible with minimum power consumption.

It supports half-duplex single-wire communication and modem operation (CTS/RTS), and also supports multi-processor communication.

DMA (direct memory access) can be used for data transmission/reception.

### 39.1 LPUART main features

- AMBA APB interface
- Full-duplex asynchronous communication
- NRZ Standard Mode (Mark/Space)
- Programmable baud rate
- 32.768 kHz clock, baud rate range 300 ~ 9600 baud/s. Higher baud rates require higher clock frequency support
- Dual clock domain: PCLK and dedicated core clock
- Data word length configurable (7 bit/8 bit/9 bit)
- Programmable data sequence, shifting MSB or LSB first
- Number of stop bits is configurable (1/2 bit)
- Single-wire Half-duplex communications
- Support continuous DMA transfer
- Independent enable for transmission and reception
- Independent polarity control for Tx/Rx signals
- Tx/Rx pins are interchangeable
- Support hardware RS - 485/modem flow control
- Transfer detection flag
  - Busy flag
  - End of transmission flags
- Parity control
  - Generate parity bits when transmitted
  - On receive parity
- 4 error flags
  - Overrun error

- Noise detection
- Frame error
- Parity error
- Interrupt sources with flags:
  - CTS change
  - Transmit data register empty
  - Transmission complete
  - Receive data register full
  - Bus idle detected
  - Overrun error
  - Framing error
  - Noise operation
  - Error detection
  - Match address byte
- Multiprocessor communication: LPUART enters silent mode when addresses do not match
- Supports silent mode wake-up (idle frame/address tag detection)

## 39.2 LPUART functional description

### 39.2.1 LPUART block diagram

Figure 39-1 LPUART block diagram

### 39.2.2 LPUART signals

Any LPUART bidirectional communications require a minimum of two pins: Receive Data In (RX) and Transmit Data Out (TX).

- RX: Receive data serial input.
- TX: Transmit data output. When the transmitter is disabled, the output pin returns to its IO port

configuration. When the transmitter is enabled but not sending data, the TX pin is high. In single-wire mode, this IO is used to transmit and receive the data.

#### Hardware flow control mode

- CTS: transmission starts at low level, and transmission ends to high level
- RTS: Low level indicates that LPUART is ready to receive data

#### RS485 hardware flow control mode

- DE: Driver enable, activates transmission from external transceiver

Note: DE and RTS multiplex the same pin

### 39.2.3 LPUART Character Description

According to the {M1, M0} configuration, there are three data lengths of 7 bit/8 bit/9 bits.

M [1: 0] = 2 'b10, 7-position;

M [1: 0] = 2 'b00: 8 bits;

M [1: 0] = 2 'b01: 9 position;

By default, the signal (TX or RX) is in a low state during start bit operation. It is in high state during the stop bit.

These values can be inverted, separately for each signal, through polarity configuration control.

Idle character definition: All 1s within 7-bit/8-bit/9-bit data length + stop bit time;

Break character definition: all zeros for 7 bit/8 bit/9 bit data length time; Disconnect the end of the frame and the transmitter inserts 2 stop bits. That is, 8-bit mode, the length of the disconnected frame is 10 bits 0; 9-bit mode, the disconnected frame length is 11 bits 0.

Transmission and reception are driven by a common baud rate generator. The transmission and reception clocks are generated when the enable bit is set for the transmitter and receiver, respectively. Below are the waveforms for each frame of different lengths.

## 7-bit word length (M = 10 ),1 Stop bit

Figure 39-2 LPUART word length programming

### 39.2.4 LPUART transmission

The LPUART transmission steps are as follows.

- Configure LPUART\_CR1. {M1, M0} to define the transmission data width (7/8/9bits);
- Configure the LPUART\_BRR register and select the baud rate;
- Configure the LPUART\_CR2. STOP register to define the number of stop bits (1/2bits);
- Configure LPUART\_CR1. UE = 1 to enable LPUART;
- When multi-processor transmission, configure LPUART\_CR3. DMAT = 1 to enable DMA;
- Configuring TE = 1, hardware inserting idle frame timing;
- Write transfers data to the LPUART\_TDR register (this operation clears the TXE bit). This operation may be repeated multiple times.
- After writing the last data to LPUART\_TDR, the software waits for TC = 1, indicating that the last frame has been sent.
- The hardware generates the transmission timing:
  - Generate a start bit and start transmission
  - Transfer shift register output data (default LSB) to the TX pin
  - Stop bits (number sent according to configuration)
- After the last frame of data is transmitted, TC = 1 (when TXE = 1) is generated. When TCIE = 1, a TC interrupt is generated.

Figure 39-3 TC/TXE behavior at transmission TC/TXE timing

**Special frame****Disconnect frame**

Setting SBKRQ = 1 will transmit a disconnect frame after the current transmission is complete. The length of the broken frame depends on the configuration of the {M1, M0} registers. After the disconnected frame is sent, the hardware will clear the SBKRQ.

**Idle line detected**

Set TE = 1 to send an idle frame before the first data frame.

**LPUART reception****39.2.4.1 Start bit detection**

After a falling edge is detected on the RX, the hardware starts detecting the start bit. When a 0 is detected in the middle of the bit, it is determined that the bit is the start bit. If 1 is detected, the noise error flag (NE) is set, the current start bit is invalid, and the start bit is re-detected.

**39.2.4.2 Data character reception**

Character reception configuration steps:

- Configure LPUART\_CR1. {M1, M0}, select a reception length;
- Configure the LPUART\_BRR register and select the baud rate;
- Configure USART\_CR2. STOP and select 1-bit or 2-bit stop bits;
- Configure LPUART\_CR1. UE = 1 to enable LPUART;
- When the multi-processor transmits, configure LPUART\_CR3. DMAR = 1 to enable DMA reception;
- Configure LPUART\_CR1. RE, enable reception, and start detecting the start bit;

When the character is received:

- Non-FIFO mode, set RXNE. Indicates that the contents of the shift register have been transferred to the RDR, i.e. the data can be read out;
- When RXNEIE = 1, an interrupt is generated;
- When receiving, if a frame error, a noise error or an overflow error is detected, setting a corresponding error flag bit;
- Multiprocessor communication:

- Non-FIFO mode, RXNE is set after each byte is received and cleared by a read operation of DMA on the received data register;
- In single buffer mode:
  - In non-FIFO mode, the software reads the LPUART\_RDR register to clear the RXNE bit. The RXNE flag can also be cleared by writing LPUART\_RQR.RXFRQ = 1. The RXNE bit must be cleared before the end of the next character reception to avoid overflow errors;

#### 39.2.4.3 Special frames and error handling

##### -Break character

When a broken frame is received, LPUART treats it as an error frame.

##### -Idle character

When an idle frame is detected, it is processed as a normal frame, and if IDLEIE = 1, an interrupt is generated.

##### - Overrun error

If the RXNE is not reset and another character is received, an overflow error occurs. Data can not be transferred from the shift register to the RDR register until the RXNE bit is cleared. The RXNE flag is set after each byte received. If the next data has been received or the previous DMA request has not been executed, the RXNE flag is still set and an overflow error occurs.

When an overflow error occurs, the following error handling is performed:

- SET ORE;
- RDR content is not lost. Reading the LPUART\_DR register can still read the previous data normally;
- The shift register contents are overwritten and subsequently received data is lost;
- If RXNEIE = 1, or EIE = 1, an interrupt is generated;
- Write ORECF = 1 clears ORE bit;

ORE is set to indicate that at least 1 piece of data has been lost. There are the following two situations:

- If RXNE = 1, the last valid data is still in the receive register RDR and can be read out;
- If RXNE = 0, the last valid data has been read away, and the RDR has no valid data to read. This can occur when new (lost) data is received while the last valid data is read in the RDR.

#### 39.2.4.4 Clock source selection

The clock source of LPUART is configured by the RCC\_CCIPR.LPUARTxSEL register. Before configuring LPUART\_CR1.UE = 1, you must configure the clock source.

The selection of the clock source determines the communication speed range.

LPUART has dual clock domains, one for the kernel clock (LPUART\_ker\_ck) and the other for the system clock (LPUART\_pclk). When used to wake up from low power, the kernel clock source is configured by the RCC\_CCIPR.LPUARTxSEL register.

When the dual clock domain is not supported, the kernel clock is the same as the system clock.

When the MCU enters low power mode and the core clock source selects low frequency, LPUART can receive data and wake up the MCU, and then the software or DMA can read the data in LPUART\_RDR.

### 39.2.4.5 Framing error

Frame errors occur when no stop bit is detected at reception, resulting in synchronization failure or large amounts of noise.

When the frame is wrong, do the following processing:

- The hardware sets the FE bit;
- Invalid data is transferred from the shift register to the LPUART\_RDR register;
- In the case of single-byte communication, no interrupt is generated. However, because the NE flag bit and the RXNE flag bit are set at the same time, the FE bit has a rising edge. In the case of multiprocessor communication, if LPUART\_CR3.EIE = 1, an interrupt will be generated.
- Write LPUART\_ICR.FECF = 1 to clear the FE flag.

### 39.2.4.6 Configure the number of stop bits

Configurable bits 1/2 stop bits:

- 1 stop bit: sampling stop bit at 8/9/10 sampling point;
- 2 stop bit: sample the 2nd stop bit after the first stop bit is sampled. The RXNE and FE flags are set after detecting the end of the 2nd stop bit. The 1st stop bit does not detect frame errors.

### 39.2.5 LPUART baud rate generation

Transmit and receive are configured with the same baud rate.

$$\text{Tx/Rx baud rate} = \frac{256 \times \text{Lpuart\_ck\_pres}}{\text{LPUARTDIV}}$$

LPUARTDIV is configured in the LPUART\_BRR register. Do not change the value of the baud rate while the communication is in progress. The LPUART\_BRR register value cannot be lower than 0x300. The frequency range of fCK is 3 ~ 4096 × baud rate.

When the LPUART clock source is LSE, the maximum baud rate is 9600 baud rate. Higher baud rates can be achieved when LPUART is clocked by a different clock source than the LSE clock. For example, the LPUART clock source frequency is 100 MHz, and the maximum achievable baud rate is about 33 Mbaud.

Table 39-1 Error calculation of programmed baud rate at Lpuart\_ker\_ck\_pres = 32,768 KHz

| Baud rate      | Lpuart_ker_ck_pres = 32,768 KHz |                                            |        |
|----------------|---------------------------------|--------------------------------------------|--------|
| Expected value | Actual value                    | Value programmed in the baud rate register | Error% |

### 39.2.6 LPUART reception tolerance

The LPUART asynchronous receiver operates correctly only if the total clock system deviation is less than the tolerance of the LPUART receiver. The causes which contribute to the total deviation are:

- DTRA: deviation due to the transmitter error (which also includes the deviation of the transmitter's local oscillator)
- DQUANT: error due to the baud rate quantization of the receiver
- DREC: deviation of the receiver local oscillator
- DTCL: deviation due to the transmission line (generally due to the transceivers which can introduce an asymmetry between the low-to-high transition timing and the high-to-low transition timing).

Need to meet:  $DTRA + DQUANT + DREC + DTCL + DWU < \text{LPUART receiver tolerance}$

Where DWU is the error caused by sampling point bias when waking up using low power mode.

Table 39-3 LPUART receiver can receive data correctly at specified maximum tolerance

| {M1, M0} bits                      | 768 < BRR < 1024 |                 | 1024 < BRR < 2048 |                 | 2048 < BRR < 4096 |                 | 4096 ≤ BRR      |                 |
|------------------------------------|------------------|-----------------|-------------------|-----------------|-------------------|-----------------|-----------------|-----------------|
| 9 bits ({M1, M0} = 01), 1 stop bit | NF is an error   | NF doesn't care | NF is an error    | NF doesn't care | NF is an error    | NF doesn't care | NF is an error  | NF doesn't care |
|                                    | 4.2% to -4.84%   | 4.21% to -4.97% | 4.25% to -4.62%   | 4.21% to -4.72% | 4.23% to -3.81%   | 4.21% to -3.97% | 1.51% to -4.01% | 1.43 to -4.03%  |

Note: When the received frame contains an idle frame that is exactly 10/11/9 bits (corresponding to M = 'b00/11/10'), the data specified in the table may vary slightly under special circumstances.

### 39.2.7 LPUART multiprocessor communication

Multi-processor communication can be realized through LPUART (connecting several LPUARTs in a network). For example, a certain LPUART device may be the master, and its TX output is connected to the RX input of other LPUART slaves; The respective TX output logic of the LPUART slaves is coupled together and connected to the RX input of the master.

An unaddressed device may configure the MME register to be put into silent mode. In silent mode:

- No receive status bits will be set;
- Disable all reception interruptions;
- LPUART\_ISR.RWU = 1. By configuring LPUART\_RQR.MMRQ, hardware and software can control LPUART to enter silent mode;

Depending on the value of LPUART\_CR1.WAKE, LPUART can enter or exit silent mode in two ways:

- WAKE = 0: Idle bus detection;
- WAKE = 1: address flag detection;

#### 39.2.7.1 Idle bus detection

When MMRQ writes 1 and RMU automatically sets 1, LPUART enters silent mode.

When an idle frame is detected, LPUART wakes up. The RWU is then cleared by hardware, but LPUART\_ISR.IDLE is not set.

Figure 39-4 Silent mode detected with bus frame

Notes:

If the MMRQ position 1 is placed when the IDLE character has passed, the silent mode will not be entered (RWU is not set to 1).

If the LPUART is activated while the line is IDLE, the idle state is detected after the duration of one IDLE frame (not only after the reception of one character frame).

### 39.2.7.2 4-bit/7-bit address flag detection

In this mode, if MSB = 1, the byte is considered an address, otherwise it is considered data. In one address byte, the address of the target receiver is placed in four or seven LSBs (several selected by the ADDM7 register). This 4-bit/7-bit address is compared by the receiver to the address configured in the ADD in the LPUART\_CR2 register.

If the received byte does not match the configured address, LPUART enters silent mode. At this time, the hardware sets the RWU. The RXNE flag is not set for this address byte and no interrupt nor DMA request is issued as the LPUART would have entered mute mode.

When MMRQ is configured to 1, LPUART also enters silent mode and sets RWU = 1.

If the received byte matches the configured address, LPUART exits silent mode. At this time, the RWU is cleared, and then data is normally received. Since the RWU has been cleared, this situation sets the RXNE/RXFNE bit.

Figure 39-5 Silent mode detected by address flags

### 39.2.8 LPUART parity

Set LPUART\_CR1.PCE = 1 to enable parity control (generate a parity bit when sending and perform parity check when receiving). According to the frame length defined by {M1, M0} bits, the supported LPUART frame formats are shown in the following table:

Table 39-4 supported LPUART frame formats

| {M1, M0} bits | PCE bit | LPUART frame                                   |
|---------------|---------|------------------------------------------------|
| 00            | 0       | Start bit   8 bit data   Stop bit              |
| 00            | 1       | Start bit   7 bit data   Parity bit   Stop bit |
| 01            | 0       | Start bit   9-bit data   Stop bit              |
| 01            | 1       | Start bit 8 bit data parity bit stop bit       |
| 10            | 0       | Start bit   7-bit data   Stop bit              |
| 10            | 1       | Start bit 6 bit data parity bit stop bit       |

**39.2.8.1 Even parity**

The even check bit causes 6, 7, or 8 pieces of LSB data in a frame and the number of "1" in the check bit to be even.

**39.2.8.2 Odd parity**

The odd check bits make 6, 7, or 8 LSB data in a frame and the number of "1" in the check bits odd.

**39.2.8.3 Receipt check**

Set PE = 1 in case of parity error and generate interrupt when PEIE = 1. The software writes PECF = 1 to clear PE.

**39.2.8.4 Transmit parity bit**

The MSB is replaced by a parity bit when transmitted.

**39.2.9 LPUART single-line half-duplex communication**

When LPUART\_CR3.HDSEL = 1 is configured, LPUART enters single-wire half-duplex communication mode.

In this mode:

- TX and RX are connected inside the module;
- The RX pin is not used;
- Release the TX pin as standard I/O when there is no data transfer

**39.2.10 DMA continuous communication**

LPUART can utilize DMA continuous communication. The DMA requests for the receive buffer and the transmit buffer are generated separately.

**39.2.10.1 Transmission using DMA**

DMA transmission is enabled by configuring LPUART\_CR3.DMAT. When TXE = 1, the DMA transfers data from the designated SRAM area to the LPUART\_DR register.

The configuration steps of DMA transmission are as follows:

- Configure SYSCFG\_CFGR3 or SYSCFG\_CFGR4 to select the DMA channel used by LPUART
- Configure the LPUART\_TDR register address as the destination address for the DMA transfer. After each TXE event, data will be transferred to this address;
- Configure a memory (e.g. SRAM) address as the source address for DMA transfers. Loading read data from this memory into the LPUART\_TDR register after each TXE event;
- Write the DMA control register to configure the number of transferred bytes;
- Write the DMA register to configure channel priority;
- Depending on the application, the configuration generates a DMA interrupt when the transmission is half or all complete;
- Write TCCF = 1 to clear the LPUART\_ISR.TC flag;
- Enable a DMA channel;

When the transmission reaches the configured number of transmission bytes, the DMA controller generates an interrupt request.

When the DMA has written all the data to be transmitted, set  $TCIF = 1$ . Then the software needs to wait for  $TC = 1$ , indicating that LPUART has sent the last frame of data.

Figure 39-6 LPUART transmitted with DMA

### 39.2.10.2 Reception using DMA

DMA reception is enabled by configuring LPUART\_CR3. DMAR. For each byte received, the DMA transfers data from the LPUART\_RDR register to the designated SRAM area.

The configuration steps of DMA reception are as follows:

- Configure SYSCFG\_CFGR3 or SYSCFG\_CFGR4 to select the DMA channel used by LPUART
- Configure the LPUART\_RDR register address as the source address for the DMA transfer. After each RXNE event, data will be transferred to memory by reading data from this LPUART\_RDR register address;
- Configure the SRAM memory address as the destination address for the DMA transfer. After each RXNE event, data will be transferred from the LPUART\_RDR register to this address;
- Write the DMA control register to configure the number of transferred bytes;
- Write the DMA register to configure channel priority;
- Depending on the application, the configuration generates a DMA interrupt when the transmission is half or all complete;
- Enable a DMA channel;

When the transmission reaches the configured number of transmission bytes, the DMA controller generates an interrupt request.

Figure 39-7 LPUART receives with DMA

### 39.2.10.3 Error flags and interrupts

In multiprocessor communication mode, any error generated during transmission will generate an error flag after the current byte transmission is completed, and an interrupt will be generated if the corresponding interrupt is enabled.

### 39.2.11 RS232 hardware flow control and RS485 driver enablement

The serial data flow of the two LPUART modules can be controlled through CTS and RTS.

Figure 39-8 Hardware Flow Control

#### 39.2.11.1 RS232 RTS Flow control

RTS flow control is enabled by configuring LPUART\_CR3. RTSE = 1. When LPUART is ready to receive data, pull RTS low. When the receive register is full, the RTS pulls high (invalid), indicating that the current frame is the last frame.

Figure 39-9 RTS flow control

### 39.2.11.2 RS232 CTS Flow control

CTS flow control is enabled by configuring LPUART\_CR3. CTSE = 1. When enabled, the CTS signal is detected before transmitting the next frame. If CTS = 0 (valid), transmit the next data (assuming there is data to be transmitted). If CTS = 1 (invalid), the current transmission is complete (before the stop bit).

When CTSE = 1, the hardware sets CTSIF as long as the CTS signal is inverted. Indicates that the receiver is ready to communicate or not. An interrupt is generated if the CTSIE bit = 1.

Figure 39-10 CTS flow control

Note: CTS maintains at least 3 LPUART source clocks high before the end of the current frame. CTSCF is also required to maintain at least  $2 \times \text{PCLK}$  cycles.

### 39.2.11.3 RS485 Driver Enable

Configure LPUART\_CR3. DEM = 1 to enable the DE function. With the DE signal, the user can activate the external transmission control. The effective polarity of the DE signal is configured by the LPUART\_CR3.DEP register.

The valid time is configured by LPUART\_CR1. DEAT and is the time between the valid edge of the DE signal and the start of the start bit.

The release time is configured by LPUART\_CR1. DEDT and is the time between the last stop bit and the DE is invalidated.

The specific time is calculated as follows, where  $P = BRR$  [20:11]:

- DE insertion time:
  - $(1 + (DEAT \times P)) \times f_{CK}$ ,  $P \neq 0$
  - $(1 + DEAT) \times f_{CK}$ ,  $P = 0$
- DE release time:
  - $(1 + (DEDT \times P)) \times f_{CK}$ ,  $P \neq 0$
  - $(1 + DEDT) \times f_{CK}$ ,  $P = 0$

### 39.2.12 LPUART low-power modes

LPUART supports low power mode, which allows data to be transferred when the LPUART PCLK is not present.

When  $UESM = 1$ , LPUART can wake up the MCU in low power mode.

#### 39.2.12.1 Generate an interrupt wake-up request according to WUS

When a wake-up event is detected, the hardware generates a WUF flag. If  $WUFIE = 1$ , a WUF interrupt is generated. In this case, setting the WUF flag to 1 is sufficient to wake up the MCU from low power mode.

Notes:

- Before entering low power mode, ensure that there is no LPUART transmission;
- Regardless of whether the MCU is in low power mode or working mode, whenever a wake-up event is detected, the WUF flag will be set;
- After initializing and enabling LPUART reception, it is necessary to confirm whether the LPUART is truly enabled through the REACK bit, and then configure to enter the low power mode;
- When DMA reception is enabled, DMA reception must be turned off before entering low power mode; Then wake up from low power and re-enable DMA;

#### 39.2.12.2 Entering low power mode from silent mode

If the LPUART is put into Mute mode before entering low-power mode:

- Silent mode cannot be awakened with idle frames because idle frame detection is not supported in low power mode;
- If the silent mode is waked up by address matching, the address matching method is also used to wake up from the low power mode. When entering low power, if  $RXNE = 1$ , LPUART will not enter the low power mode, but will remain in the silent mode;

#### 39.2.12.3 Kernel clock off in low power mode

If the kernel clock is also turned off in low power mode, LPUART generates an `LPUART_ker_ck_req` signal to enable the kernel clock when it detects a falling edge on the RX line.

If the wake-up event `LPUART_CR3.WUS` is configured to address match:

- After the core clock is enabled, if the addresses match after receiving one frame, the MCU wakes up and starts normal data reception;

The following figure shows the address verification match after the wake-up event:

Figure 39-11 LPUART address matching wakeup

If the address validation does not match after the wake-up event, the core clock shuts down again, the MCU does not wake up, and the system remains in low power mode.

Figure 39-12 LPUART address does not match and cannot wake up

### 39.3 LPUART interrupts

| Interrupt event                                                      | Event flag                                | Enable Control bit                                    | Interrupt zero-ing                                          | Is the interrupt signal valid |         |
|----------------------------------------------------------------------|-------------------------------------------|-------------------------------------------------------|-------------------------------------------------------------|-------------------------------|---------|
|                                                                      |                                           |                                                       |                                                             | Interrupts and events         | Wake-up |
| Transmit data register empty                                         | TXE                                       | TXEIE                                                 | Write data to TDR                                           | YES                           | NO      |
| CTS interrupts                                                       | CTSIF                                     | CTSIE                                                 | Software configuration CTSCF = 1                            | YES                           | NO      |
| Transmission is complete                                             | TC                                        | TCIE                                                  | Write data to TDR or TCCF = 1                               | YES                           | NO      |
| Receive register is not empty (read data is ready)                   | RXNE<br>(Corresponding to flag bit RXFNE) | RXNEIE<br>(corresponding to interrupt enable RXFNEIE) | Read RDR register or RXFRQ = 1                              | YES                           | YES     |

| 31: 24 | ADD [7: 0]     | RW  | 8'b0        | Address of the LPUART node<br>This register is used in multiprocessor silent or stop mode and is used as an address when the address wakes up. The MSB bit sent by the transmitter is 1. In normal receive mode, this register is used for character detection. At this time, the received content is compared with ADD [7: 0], and if it matches, the CMF flag bit is set.<br>This register can only be written if RE = 0 or UE = 0. |

|        |          |   |                                   |                                                                                                                                                                                                                                                                                                                                                            |
|--------|----------|---|-----------------------------------|------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
|        |          |   | default 1, otherwise by default 0 | Note: This bit is 0 when FIFO_EN is turned off                                                                                                                                                                                                                                                                                                             |
| 22     | REACK    | R | 0                                 | Receive an enable acknowledgement flag. Hardware sets/resets this register. Indicates that the hardware is ready to receive before entering low power mode. This bit is reserved if LPUART does not support wake-up from stop low power mode.                                                                                                              |
| 21     | TEACK    | R | 0                                 | Send an enable acknowledgement flag. Hardware sets/resets this register. This register may be used when writing TE = 0 in the LPUART_CR1 register to generate an idle frame request, and then writing TE = 1 to satisfy the minimum period of TE = 0.                                                                                                      |
| 20     | WUF      | R | 0                                 | Wake up flag from low power mode. The hardware writes this bit as 1 when a wake-up event is detected. The event is defined by the WUS bitfield. This bit is cleared by software by writing 1 to WUCF in the LPUART_ICR register. If WUFIE = 1 in the LPUART_CR3 register, an interrupt is generated. Note: When UESM is cleared, WUF flag is also cleared. |
| 19     | RWU      | R | 0                                 | Received silent mode wake-up. The register is set when a silent mode sequence is received; If a wake-up sequence is received, the register is cleared. The specific wake-up sequence (address tag or idle frame) is controlled by the register LPUART_CR1. WAKE bit.<br>0: The receiver is in the working mode;<br>1: The receiver is in silent mode;      |
| 18     | SBKF     | R | 0                                 | Send abort flag. This register indicates that the disconnect character is requested to be sent. This register is set by writing 1 to the LPUART_RQR.SBKRQ register by software. The hardware clears the register after sending the stop bit of the abort character.<br>0: No disconnect character is transmitted;<br>1: Send disconnect character;         |
| 17     | CMF      | R | 0                                 | Address match flag. This register is set when a character matching the ADD [7: 0] value is received. Software writing 1 to the CMCF register clears the bit.                                                                                                                                                                                               |
| 16     | BUSY     | R | 0                                 | Busy flag<br>When the RX line receives data (the start bit is correctly received), the hardware sets this register. When the reception is completed, the hardware clears the register.<br>0: LPUART idle;<br>1: Reception is in progress;                                                                                                                  |

## 40. Clock trimming controller (CTC)

### 40.1 Introduction

The clock calibration controller (CTC) uses hardware to automatically calibrate the internal 48 MHz RC crystal oscillator (HSI48). When the OTG\_FS module uses the HSI48 clock as the clock source, the HSI48 clock frequency must be in the range of  $48 \text{ MHz} \pm 0.25\%$ , but the internal crystal oscillator without calibration cannot meet such high accuracy. The CTC module calibrates the clock frequency of HSI48 based on an external high-precision reference signal source, and obtains an accurate HSI48 clock by automatically or manually adjusting the calibration value.

### 40.2 Main Features

The CTC module provides the following functions:

- Three external reference signal sources: GPIO, LSE clock, USB\_SOF signal from OTG\_FS module
- Providing software reference synchronization pulses;
- Automatic hardware calibration, no software operation required;
- 16-bits calibration counter with reference source capture and reload;
- 8-bits clock calibration base value for frequency evaluation and automatic calibration;
- Flag bits and interrupts that indicate the state of clock calibration: calibration success state (CKOKIF), warning state (CKWARNIF), and error state (ERRIF).

#### 40.2.1 CAN block diagram

## 40.3 Functional description

### 40.3.1 REF synchronous pulse generator

First, the reference signal source: GPIO, LSE clock output or USB\_SOF is selected by setting the REFSEL bit in the CTC\_CTL1 register (CTC control register 1).

The signal polarity at the time of synchronization of the reference signal source can then be configured by setting the REFPOL bit in the CTC\_CTL1 register, and a suitable synchronization clock frequency signal can be generated by setting the REFPSC bit in the CTC\_CTL1 register.

If you need to use a software reference pulse signal, you need to set the SWREFPUL bit in the CTC\_CTL0 register (CTC control register 0) to 1. The software reference pulse signal and the external reference pulse signal are finally logically OR operated.

### 40.3.2 CTC calibration counter

The CTC clock calibration counter is clocked by HSI 48. After setting the CNTEN bit in the CTC\_CTL0 register, when the first reference synchronization pulse signal is detected, the counter starts counting down from the RLVALUE value (RLVALUE is defined in the CTC\_CTL1 register). Each time a reference synchronization pulse signal is detected, the counter reloads the RLVALUE value and resumes counting down. If the reference sync pulse signal is always not detected, the counter counts down to zero, then up to  $128 \times \text{CKLIM}$  (CKLIM is defined in CTC\_CTL1), and finally stops until the next reference sync pulse signal is detected. Once the reference synchronization pulse signal is detected, the count value of the current CTC calibration counter is captured and stored in the REFCAP bit in the CTC\_SR register, while the count direction of the current counter is stored in the REFDIR bit in the CTC\_SR register. The details are shown in the figure below.

### 40.3.3 Frequency evaluation and automatic calibration process

When the reference synchronization pulse signal appears, the clock frequency evaluation function starts to be executed. If the reference synchronization pulse signal appears during the counter counting down, the current clock frequency is slower than the expected clock frequency (frequency 48M), and the TRIMVALUE value (clock calibration value) in CTC\_CTL0 needs to be increased. If the reference synchronization pulse signal appears in the process of counting up the counter, it means that the current clock frequency is faster than the expected clock frequency, and the TRIMVALUE value needs to be reduced. The CKOKIF bit, CKWARNIF bit, CKERR bit, and REFMIS bit in the CTC\_SR register reflect the status of the frequency evaluation.

If the AUTOTRIM position in CTC\_CTL0 is 1, the hardware enables auto-calibration mode. In this mode, if the reference synchronization pulse signal appears during the counter counting down, it means that the current clock frequency is slower than the expected clock frequency, and the TRIMVALUE value in CTC\_CTL0 will automatically increase to increase the current clock frequency. On the contrary, if the reference synchronization pulse signal appears during the counter counting up, it means that the current clock frequency is faster than the expected clock frequency, and the TRIMVALUE value will automatically decrease, thereby decreasing the current clock frequency.

- When the value of the counter is  $< \text{CKLIM}$ , the reference synchronization pulse signal is detected:

The CKOKIF bit (clock calibration success flag bit) in the CTC\_SR register is set, and if the CKOKIE bit (clock calibration complete interrupt enable bit) in the CTC\_CTL0 register is set to 1, an interrupt will be generated. If AUTOTRIM in the CTC\_CTL0 register is set to 1, the TRIMVALUE value in the CTC\_CTL0 register does not change.

- When the value of  $\text{CKLIM} \leq \text{counter} < 3 \times \text{CKLIM}$ , the reference synchronization pulse signal is detected:

The CKOKIF bit in the CTC\_SR register is set, and an interrupt will be generated if the CKOKIE position 1 in the CTC\_CTL0 register. If the AUTOTRIM position in the CTC\_CTL0 register is 1, the TRIMVALUE value in the CTC\_CTL0 register will be incremented by 1 during counter down and decremented by 1 during counter up.

- When the value of  $3 \times \text{CKLIM} \leq \text{counter} < 128 \times \text{CKLIM}$ , the reference synchronization pulse signal is detected:

The CKWARNIF bit (clock calibration warning interrupt bit) in the CTC\_SR register is set, while an interrupt will be generated if the CKWARNIE bit (clock calibration warning interrupt enable bit) in the CTC\_CTL0 register is set to 1. If the AUTOTRIM position in the CTC\_CTL0 register is 1, the TRIMVALUE value in the CTC\_CTL0 register will be incremented by 2 during counter down and subtracted by 2 during counter up.

- The value of the counter is  $\geq 128 \times \text{CKLIM}$ , and the reference synchronization pulse signal is detected during the counter counting down:

The CKERR bit (clock calibration error bit) in the CTC\_SR register is set, and if the ERRIE bit (error interrupt enable bit) in the CTC\_CTL0 register is set to 1, an interrupt will be generated. The TRIMVALUE value in the CTC\_CTL0 register does not change.

- Value of counter = 128 x CKLIM, counter during up count:

The REFMIS bit (REF sync pulse loss bit) in the CTC\_SR register is set, and an interrupt will be generated if the ERRIE position 1 in the CTC\_CTL0 register. The TRIMVALUE value in the CTC\_CTL0 register does not change.

If the calibration value of TRIMVALUE in the CTC\_CTL0 register is greater than 127, an overflow event will occur, and if the calibration value of TRIMVALUE is less than 0, an underflow event will occur. The value range of TRIMVALUE is 0 to 127 (when an overflow event occurs, the TRIMVALUE value is 127; when an underrun event occurs, the TRIMVALUE value is 0). Then, the TRIMERR bit (calibration value error bit) in the CTC\_SR register will be set, and if the ERRIE position 1 in the CTC\_CTL0 register, an interrupt will be generated.

#### 40.3.4 Software Programming Guide

The RLVALUE bit and CKLIM bit in the CTC\_CTL1 register are key to clock frequency evaluation and hardware automatic calibration. Their values are calculated from the frequency of the desired clock (HSI 48: 48 MHz) and the frequency of the reference synchronization pulse signal. The ideal state is that the reference synchronization pulse signal appears when the CTC counter counts to zero, so the value of RLVALUE is:

$$RLVALUE = (f_{clock} \div f_{REF}) - 1$$

The value of CKLIM is set by the user according to the accuracy of the clock. It is generally recommended to set it to half of the step size, so the value of CKLIM is:

$$CKLIM = (f_{clock} \div f_{REF}) \times 0.12\% \div 2$$

A typical step size value is 0.12%, fclock is the frequency of the desired clock (48 MHz), and fREF is the frequency of the reference synchronization pulse signal.

TRIMVALUE in the CTC\_CTL0 register can be written by software when the AUTOTRIM bit is 0, but modifying TRIMVALUE will directly affect the frequency of the HSI48M clock. Therefore, TRIMVALUE should not be modified by software at will. It is recommended that the user judge and modify according to the flag bit between the two reference signals; Alternatively, if a reliable value already exists, the user can directly modify the value of HSI48 TRIM in the RCC\_CFGR1 register.

#### 40.4.2 CTC Control Register 1 (CTC\_CTL1)

Address offset: 0x04

Reset value: 0x2022 BB7F

This register can only be accessed word-wise (32-bit). When CNTEN is 1, the value of this register cannot be modified.

## 41. Random Number Generator (RNG)

### 41.1 Overview

RNG is a random number generator. The user can enable and turn off the random source of RNG by configuring the control register. The random number needs to wait for the DATA\_RDY position bit before it can be read.

#### 41.1.1 Main features

The DMA supports:

- Has 2 independent random sources.
- The random number generated by the random source is post-processed using the linear feed-back shift register (LFSR), and a 32-bit random number is generated after 32 clock cycles.

#### 41.1.2 Top-level structure diagram

Figure 41-1 RNG top-level module block diagram

## 41.2 Functional description

### 41.2.1 Generation of random numbers

Figure 41-2 RNG random number generation model block diagram

After enabling the RNG random source (RNG\_CR = 0x1/2/3), the RNG random source will generate a 1-bit random number every clock cycle, and each random number will be processed by the linear feedback shift register. After 32 clock cycles, a 32-bit random number will be generated.

### 41.2.2 Software operation of RNG

Take enabling only random source 0 as an example:

1. Turn on the clock of the RNG module;
2. Setting the control register RNG\_CR to 0x01;
3. Waiting for the DATA\_RDY position bit in the RNG\_SR register;
4. Reads the random number in the RNG\_DR register.

### 41.2.3 Random Source of RNG

RNG has two random sources:

The random source 0 is generated by XOR the output of a ring oscillator formed by two sets of multiple free-running NAND gates;

The random source 1 is generated by the exclusive OR of the output of a ring oscillator formed by a set of a plurality of free-running same-OR gates.

## 41.3 TIMx registers

The register width is 32bits.

## 42. AES Hardware Accelerator (AES)

### 42.1 Introduction

The AES Hardware Accelerator (AES) encrypts or decrypts data using algorithms and implementations that fully comply with the Advanced Encryption Standard (AES) defined in Federal Information Processing Standards (FIPS) Publication 197.

AES supports CTR, GCM, CMAC, CCM, ECB, and CBC chain modes with 128-bit or 256-bit key lengths.

AES is an AMBA AHB slave peripheral that is only accessible via 32-bit single-time.

The peripheral supports DMA single transfer of incoming and outgoing data.

#### 42.1.1 Main Features

- Supports 128-bit and 256-bit key lengths
- Encryption and decryption based on multiple chain modes
  - Crypto Blockchain CBC
  - Electronic codebook ECB
  - Counter CTR
  - Galois counter CCM,
  - Galois message authentication code CMAC
  - CBC-MAC Counter GCM Mode
- Data is big endian aligned
- The data input and output can be operated using DMA

#### 42.1.2 CAN block diagram

Figure 42-1 AES module block diagram

## 42.2 Function description

### 42.2.1 ECB Mode

A basic electronic codebook (ECB) mode of operation in which input data is passed directly to the basic encryption core and the output of the encryption core is passed directly to the output buffer. For decryption, the encryption core operates in reverse.

### 42.2.2 CBC Feedback Mode

A cryptographic blockchain (CBC) feedback mode of operation in which input data is XOR with an initialization vector (IV) before being passed to the base cryptographic core. The output of the encryption core passes directly to the output buffer and becomes the next IV. For decryption, the encryption operation is reversed, and the encryption core output is XOR. The input ciphertext of the current operation is the IV of the next operation.

### 42.2.3 CTR Mode

Operating mode of Counter (CTR). This operation will encrypt the IV. The output of the encryption core (encryption IV) is exclusively OR with the data to produce an output result. IV consists of two parts, a fixed part and a counter part. The counter portion increases with each block. The counter width varies depending on the context and may be 16, 32, 64, 96, or 128 bits wide. Note that in this mode, encryption and decryption use the same cryptographic operation.

#### 42.2.4 CMAC Authentication Mode

CMAC authentication mode in which the input of the encryption core is XOR with the IV. The output of the cryptographic core is then fed back as the IV of the next block. The last data input block and additional data (stored in the temporary buffer) and IV are XOR processed, and the XOR result is encrypted to output the result (TAG).

#### 42.2.5 GCM Operation

The above diagram illustrates one round of GCM operations for encryption and decryption. A 32-bit counter is used as IV (as it is for CTR mode). The data is encrypted in the same manner as in CTR mode by XOR the encryption core output with the input. After encryption/decryption, the ciphertext is XOR with the intermediate authentication result. The XOR result is used as input for the polynomial multiplication to create the next (intermediate) authentication result.

42.2.6 CCM Operation

The figure above shows one round of CCM (counter with CBC-MAC) operation for encryption and decryption. A 32-bit counter is used as IV (as it is for CTR mode). Data is encrypted in the same way as CTR mode, by XOR the encryption core output and input. The plaintext is exclusively OR with the intermediate authentication result directly after the cryptographic operation, and the exclusive OR result is used as input for the second cryptographic operation to calculate the next (intermediate) authentication result.

## 42.3 TIMx registers

AES register base address: 0x4800\_2400

| Offset address | Pin name            | Description                                     |

## 43. CORDIC Coprocessor (CORDIC)

### 43.1 Overview

CORDIC coprocessors provide hardware acceleration of mathematical functions (mainly trigonometric, hyperbolic) commonly used in motor control, metrology, signal processing, and many other applications.

Compared to software implementations, it speeds up the computation of these functions so that the processor can use lower operating frequencies or use no processor resources to perform other tasks.

#### 43.1.1 Main features

The main features are as follows:

- 24-bit CORDIC
- Circumferential and hyperbolic systems
- Rotation and vector modes
- Functions: sine, cosine, sinh, cosh, atan, atan2, atanh, modulus, square root, natural
- Programmable accuracy
- Low latency AHB interface
- After entering the required data, the results can be read directly (bus suspended) without polling or interrupting
- It also supports polling, interrupt, DMA and other reading results methods
- DMA read and write channel
- Multiple register reads/writes via DMA

### 43.2 Functional description

#### 43.2.1 Overview

CORDIC is an efficient stepwise approximation algorithm for computing trigonometric and hyperbolic functions.

In triangular (circular) mode, the sine and cosine of the angle are determined  $\theta$  by rotating the unit vector  $[1, 0]$  through a gradually decreasing angle until the cumulative sum of the rotated angles is equal to the input angle  $\theta$ . The rotation vectors  $x$  and  $y$  correspond to  $\theta$  the cosine and sine of, respectively. In turn, the angle of  $\arctangent(y/x)$  the vector  $[x, y]$  is that the unit vector  $[1, 0]$  is obtained by rotating  $[x, y]$  by a decreasing angle. The cumulative sum of the rotation angles is the angle of the original vector.

The CORDIC algorithm can also be used to compute hyperbolic functions (sinh, cosh, atanh) by replacing a continuous circular rotation with a rotation along a hyperbola.

Other functions can be derived from the basic functions described above.

#### 43.2.2 CORDIC function

The first step in using a coprocessor is to select the desired function by programming the CORDIC\_CSR register FUNC accordingly.

Table 43 -1 List of functions supported by the CORDIC coprocessor

| Function              | Primary argument (ARG1) | Secondary argument (ARG2) | Primary result (RES1) | Secondary result (RES2) |
|-----------------------|-------------------------|---------------------------|-----------------------|-------------------------|
| Cosine                | Angle $\theta$          | modulus m                 | $m * \cos\theta$      | $m * \sin\theta$        |
| Sine                  | Angle $\theta$          | modulus m                 | $m * \sin\theta$      | $m * \cos\theta$        |
| Phase                 | x                       | y                         | $\text{atan2}(y, x)$  | $\sqrt{x^2 + y^2}$      |
| Modulus               | x                       | y                         | $\sqrt{x^2 + y^2}$    | $\text{atan2}(y, x)$    |
| Arctangent            | x                       | none                      | $\tan^{-1} x$         | none                    |
| Hyperbolic cosine     | x                       | none                      | $\cosh x$             | $\sinh x$               |
| Hyperbolic sine       | x                       | none                      | $\sinh x$             | $\cosh x$               |
| Hyperbolic arctangent | x                       | none                      | $\tanh^{-1} x$        | none                    |
| Natural logarithm     | x                       | none                      | $\ln x$               | none                    |
| Square root           | x                       | none                      | $\sqrt{x}$            | none                    |

There are several functions that require two input arguments (ARG1 and ARG2), and some functions generate two results simultaneously (RES1 and RES2). For example, when converting from polar coordinates to rectangular coordinates:  $\sin\theta$  also generates  $\cos\theta$ , and  $\cos\theta$  also generates  $\sin\theta$ . The same is true for rectangular to polar transformations (phase (x, y), modulus (x, y)) and hyperbolic functions ( $\cosh\theta$ ,  $\sinh\theta$ ).

Note: The exponential function,  $\exp x$ , can be taken as the sum of  $\sinh x$  and  $\cosh x$ .

Furthermore, the logarithm of base N,  $\log_N x$ , can be obtained by multiplying  $\ln x$  by the constant K, where  $K = 1/\ln N$ .

For some functions (atan, log, sqrt), a scaling factor (see Section 43.2.4) can be applied to extend the range of the function beyond the maximum [-1, 1] range supported by the q1.31 fixed point format.

The scaling factor must be set to 0 for all other circular functions and 1 for hyperbolic functions.

#### 43.2.2.1 Cosine

Table 43-2 Cosine parameters

| Parameter | Description                                                   | Range   |
|-----------|---------------------------------------------------------------|---------|
| ARG1      | The angle $\theta$ in radians and has been divided by $\pi$ . | [-1, 1] |
| ARG2      | Modulus m                                                     | [0, 1]  |
| RES1      | $m * \cos\theta$                                              | [-1, 1] |
| RES2      | $m * \sin\theta$                                              | [-1, 1] |
| SCALE     | Not applicable                                                | 0       |

This function is used to calculate the cosine of an angle ranging from  $-\pi$  to  $\pi$ . It can also be used to perform transformations from polar coordinates to rectangular coordinates.

The main parameter is the angle in radians  $\theta$ . Before programming ARG1, it must be divided by  $\pi$ .

The second parameter is the modulus m. If m is greater than 1, it must be scaled in software to adapt it to the q1.31 range of ARG2.

The main result, RES1, is the cosine of the angle, multiplied by the modulus m.

The secondary result, RES2, is the sine of the angle, multiplied by the modulus m.

### 43.2.2.2 Sine

Table 43-3 Sine parameters

| Parameter | Description                                                 | Range     |
|-----------|-------------------------------------------------------------|-----------|
| ARG1      | The value of the angle $\theta$ in radians divided by $\pi$ | $[-1, 1]$ |
| ARG2      | Modulus $m$                                                 | $[0, 1]$  |
| RES1      | $m * \sin\theta$                                            | $[-1, 1]$ |
| RES2      | $m * \cos\theta$                                            | $[-1, 1]$ |
| SCALE     | Not applicable                                              | 0         |

This function is used to calculate the cosine of an angle ranging from  $-\pi$  to  $\pi$ . It can also be used to perform transformations from polar coordinates to rectangular coordinates.

The main parameter is the angle in radians  $\theta$ . Before programming ARG1, it must be divided by  $\pi$ .

The second parameter is the modulus  $m$ . If  $m$  is greater than 1, it must be scaled in software to adapt it to the q1.31 range of ARG2.

The primary result, RES1, is the sine of the angle, multiplied by the modulus  $m$ .

The secondary result, RES2, is the cosine of the angle, multiplied by the modulus  $m$ .

### 43.2.2.3 Phase

Table 43-4 Phase parameters

| Parameter | Description                                                   | Range     |
|-----------|---------------------------------------------------------------|-----------|
| ARG1      | x coordinate                                                  | $[-1, 1]$ |
| ARG2      | y-coordinate                                                  | $[-1, 1]$ |
| RES1      | The value of phase angle in radians $\theta$ divided by $\pi$ | $[-1, 1]$ |
| RES2      | Modulus $m$                                                   | $[0, 1]$  |
| SCALE     | Not applicable                                                | 0         |

### 43.2.2.4 Modulus

Table 43-5 Modulus parameters

| Parameter | Description                                                             | Range     |
|-----------|-------------------------------------------------------------------------|-----------|
| ARG1      | x coordinate                                                            | $[-1, 1]$ |
| ARG2      | y-coordinate                                                            | $[-1, 1]$ |
| RES1      | Modulus $m$                                                             | $[0, 1]$  |
| RES2      | The value of phase angle expressed in radians $\theta$ divided by $\pi$ | $[-1, 1]$ |
| SCALE     | Not applicable                                                          | 0         |

This function calculates the size, or modulo, of the vector  $v = [x \ y]$ . It can also be used to perform rectangular coordinate to polar coordinate conversion.

The main parameter is the x-coordinate, i.e. the magnitude of the vector in the x-axis direction. If  $|x| > 1$ , scaling must be applied in the software to fit the q1.31 range of ARG1.

The secondary parameter is the y-coordinate, i.e. the magnitude of the vector in the y-axis direction. If  $|y| > 1$ , scaling must be applied in the software to fit the q1.31 range of ARG2.

The main result, RES1, is the modulus and is given by:  $|v| = \sqrt{x^2 + y^2}$ . RES1 is limited to 1.

The secondary result, RES2, is the phase angle  $\theta$  of the vector  $v$ . RES2 must be  $\pi$  multiplied to get the angle in radians. Note that due to the cyclic nature of the phase angle,  $\pi$  close values may sometimes circle back to  $-\pi$ .

### 43.2.2.5 Arctangent

Table 43-6 Arctangent parameters

| Parameter | Description                                                     | Range   |
|-----------|-----------------------------------------------------------------|---------|
| ARG1      | $x * 2^{-n}$                                                    | [-1, 1] |
| ARG2      | Not applicable                                                  | -       |
| RES1      | The value of $2^{-n} * \tan^{-1} x$ divided by $\pi$ in radians | [-1, 1] |
| RES2      | No                                                              | -       |
| SCALE     | n                                                               | [0 7]   |

This function calculates the arctangent of the input argument x.

The main parameter ARG1 is the input value  $x = \tan \theta$ . If  $|x| > 1$ , a scaling factor of  $2^{-n}$  must be applied in the software such that  $-1 < x \cdot 2^{-n} < 1$ . The scaled value  $x \cdot 2^{-n}$  is programmed into ARG1, and the scaling factor n must be programmed into the SCALE parameter.

Note that the maximum input value allowed is  $\tan \theta = 128$ , corresponding to angle  $\theta = 89.55$  degrees.

For  $|x| > 128$ , a software method must be used to find  $\tan^{-1} x$ .

Secondary parameter, ARG2, is not used.

The primary result, RES1, is angle  $\theta = \tan^{-1} x$ . RES1 must be multiplied by  $2^n \pi$  to get the angle in radians.

Secondary outcome, RES2, not used.

### 43.2.2.6 Hyperbolic cosine

Table 43-7 Hyperbolic cosine parameters

| Parameter | Description        | Range          |
|-----------|--------------------|----------------|
| ARG1      | $x * 2^{-n}$       | [-0.559 0.559] |
| ARG2      | Not applicable     |                |
| RES1      | $2^{-n} * \cosh x$ | [0.5 0.846]    |
| RES2      | $2^{-n} * \sinh x$ | [-0.683 0.683] |
| SCALE     | n                  | 1              |

This function calculates the hyperbolic cosine of the hyperbolic angle x. It can also be used to calculate exponential functions  $e^x = \cosh x + \sinh x$ , and  $e^{-x} = \cosh x - \sinh x$ .

The main parameter is the hyperbolic angle x. Only x values in the range of -1.118 to +1.118 are supported. Since the minimum value of  $\cosh x$  is 1, which is outside the range of the q1.31 format, a scaling factor of  $2^{-n}$  must be applied in the software. The scaling factor  $n = 1$  must be programmed into the SCALE parameter.

Secondary parameters are not used.

The primary result, RES1, is the hyperbolic cosine,  $\cosh x$ . RES1 must be multiplied by 2 to get the correct result.

The secondary result, RES2, is the hyperbolic sine,  $\sinh x$ . RES2 must be multiplied by 2 to get the correct result.

### 43.2.2.7 Hyperbolic sine

Table 43-8 Hyperbolic sine parameters

| Parameter | Description        | Range           |
|-----------|--------------------|-----------------|
| ARG1      | $x * 2^{-n}$       | [-0.559, 0.559] |
| ARG2      | Not applicable     | -               |
| RES1      | $2^{-n} * \sinh x$ | [-0.683, 0.683] |
| RES2      | $2^{-n} * \cosh x$ | [0.5, 0.846]    |
| SCALE     | n                  | 1               |

This function calculates the hyperbolic cosine of the hyperbolic angle x. It can also be used to calculate exponential functions  $e^x = \cosh x + \sinh x$ , and  $e^{-x} = \cosh x - \sinh x$ .

The main parameter is the hyperbolic angle x. Only x values in the range of -1.118 to +1.118 are supported. Since the minimum value of  $\cosh x$  is 1, which is outside the range of the q1.31 format, a scaling factor of  $2^{-n}$  must be applied in the software. The scaling factor  $n = 1$  must be programmed into the SCALE parameter.

Secondary parameters are not used.

The primary result, RES1, is the hyperbolic cosine,  $\sinh x$ . RES1 must be multiplied by 2 to get the correct result.

The secondary result, RES2, is the hyperbolic sine,  $\cosh x$ . RES2 must be multiplied by 2 to get the correct result.

### 43.2.2.8 Hyperbolic arctangent

Table 43-9 Hyperbolic arctangent parameters

| Parameter | Description                       | Range          |
|-----------|-----------------------------------|----------------|
| ARG1      | $x * 2^{-n}$                      | [-0.403 0.403] |
| ARG2      | Not applicable                    | -              |
| RES1      | $2^{-n} * \operatorname{atanh} x$ | [-0.559 0.559] |
| RES2      | Not applicable                    | -              |
| SCALE     | n                                 | 1              |

This function calculates the hyperbolic arc tangent of the input argument x.

The main argument is the input value x. Only x values in the range of -0.806 to +0.806 are supported. The value of x must be scaled by a factor of  $2^{-n}$ , where  $n = 1$ . The scaled value  $x * 0.5$  is programmed into ARG1 and the scaling factor  $n = 1$  must be programmed into the SCALE parameter.

Secondary parameters are not used.

The primary outcome is the hyperbolic arc tangent value  $\operatorname{atanh} x$ . RES1 must be multiplied by 2 to get the correct value.

Secondary results were not used.

### 43.2.2.9 Natural logarithm

Table 43-10 Natural logarithm parameters

| Parameter | Description          | Range          |
|-----------|----------------------|----------------|
| ARG1      | $x * 2^{-n}$         | [0.054 0.875]  |
| ARG2      | Not applicable       | -              |
| RES1      | $2^{-(n+1)} * \ln x$ | [-0.279 0.137] |
| RES2      | Not applicable       | -              |
| SCALE     | n                    | [1 4]          |

This function calculates the natural logarithm of the input argument x.

The main argument is the input value x. Only x values in the range of 0.107 to 9.35 are supported.

The value of x must be scaled by a factor of  $2^{-n}$  such that  $x * 2^{-n} < 1 - 2^{-n}$ . The scaled value  $x * 2^{-n}$  is programmed into ARG1 and the scaling factor n must be programmed into the SCALE parameter.

The following table lists the valid scaling factor n, along with the corresponding ranges of x and ARG1.

Table 43-11 Scaling factors in natural logarithm and their corresponding ARG1 and x ranges

| n | x range              | ARG1 range                           |
|---|----------------------|--------------------------------------|
| 1 | $0.107 \leq x < 1$   | $0.0535 \leq \text{ARG1} < 0.5$      |
| 2 | $1 \leq x < 3$       | $0.25 \leq \text{ARG1} < 0.75$       |
| 3 | $3 \leq x < 7$       | $0.375 \leq \text{ARG1} < 0.875$     |
| 4 | $7 \leq x \leq 9.35$ | $0.4375 \leq \text{ARG1} \leq 0.584$ |

Secondary parameters are not used.

The primary outcome is the natural logarithm,  $\ln x$ . RES1 must be multiplied by  $2^{-(n+1)}$  to get the correct value.

Secondary results were not used.

### 43.2.2.10 Square root

Table 43-12 Square root parameters

| Parameter | Description         | Range         |
|-----------|---------------------|---------------|
| ARG1      | $x * 2^{-n}$        | [0.027 0.875] |
| ARG2      | Not applicable      | -             |
| RES1      | $\sqrt{x} * 2^{-n}$ | [0.04 1]      |
| RES2      | Not applicable      | -             |
| SCALE     | n                   | [0 2]         |

This function calculates the square root of the input argument x.

The main argument is the input value x. Only x values in the range of 0.027 to 2.34 are supported.

The value of x must be scaled by a factor of  $2^{-n}$  such that  $x * 2^{-n} < (1 - 2^{-(n-2)})$ .

The scaled value  $x * 2^{-n}$  is programmed into ARG1, and the scaling factor n must be programmed into the SCALE parameter.

Table 43-13 The scaling factor in the square root of the table and its corresponding ARG1 and x ranges

| n | x range                  | ARG1 range                           |
|---|--------------------------|--------------------------------------|
| 0 | $0.027 \leq x < 0.75$    | $0.027 \leq \text{ARG1} < 0.75$      |
| 1 | $0.75 \leq x < 1.75$     | $0.375 \leq \text{ARG1} < 0.875$     |
| 2 | $1.75 \leq x \leq 2.341$ | $0.4375 \leq \text{ARG1} \leq 0.585$ |

Secondary parameters are not used.

The primary result is the square root of  $x$ . RES1 must be multiplied by  $2^{-n}$  to get the correct value.

Secondary results were not used.

#### 43.2.3 Fixed-point representation

CORDIC operates in a fixed-point signed integer format. The input and output values can be in q1.31 or q1.15 format.

In q1.31 format, numbers are represented by one sign bit and 31 decimal places (binary decimal places). Therefore, the range of values is -1 (0x80000000) to 1-2<sup>-31</sup> (0x7FFFFFFF).

In the q1.15 format, the values range from -1 (0x8000) to 1-2<sup>-15</sup> (0x7FFF). The advantage of this format is that the two q1.15 input parameters can be packed into a 32-bit write and the two results can be fetched in a 32-bit read.

#### 43.2.4 Scaling factor

Several of the functions listed in the CORDIC functions section specify a scaling factor SCALE. This allows the input range of the function to be extended to the range supported by CORDIC without overflowing the input, output, or internal registers. If a scaling factor is required, it must be calculated in software and programmed into the SCALE field of the CORDIC\_CSR register. Before writing to the CORDIC\_WDATA register, the input parameters must be scaled accordingly. After reading the result from the CORDIC\_RDATA register, the result must also be scaled.

Note: The scaling factor causes a loss of scaling value accuracy.

#### 43.2.5 Accuracy

The accuracy of the results depends on the number of CORDIC iterations. See picture below.

CORDIC can perform two iterations per clock cycle. For each function, the following table represents the maximum error remaining after every four iterations, and the number of clock cycles needed to achieve this accuracy. From this table, the required number of cycles can be determined and programmed in the precision field of the CORDIC\_CSR register.

Once the configured number of iterations is completed, the coprocessor stops immediately and the result can be read immediately.

Table 43-14 precision and number of iterations

| Function                                                        | Number of iterations | Number of cycles | Max residual error <sup>(1)</sup> |                  |
|-----------------------------------------------------------------|----------------------|------------------|-----------------------------------|------------------|
|                                                                 |                      |                  | q1.31 format                      | q1.15 format     |
| Sin, Cos,<br>Phase <sup>(2)</sup> ,<br>Mod, Atan <sup>(4)</sup> | 4                    | 1                | 2 <sup>-3</sup>                   | 2 <sup>-3</sup>  |
|                                                                 | 8                    | 2                | 2 <sup>-7</sup>                   | 2 <sup>-7</sup>  |
|                                                                 | 12                   | 3                | 2 <sup>-11</sup>                  | 2 <sup>-11</sup> |
|                                                                 | 16                   | 4                | 2 <sup>-15</sup>                  | 2 <sup>-15</sup> |
|                                                                 | 20                   | 5                | 2 <sup>-18</sup>                  | 2 <sup>-16</sup> |
|                                                                 | 24                   | 6                | 2 <sup>-19</sup>                  | 2 <sup>-16</sup> |
| Sinh, Cosh,<br>Atanh, Ln <sup>(3)</sup>                         | 4                    | 1                | 2 <sup>-2</sup>                   | 2 <sup>-2</sup>  |
|                                                                 | 8                    | 2                | 2 <sup>-6</sup>                   | 2 <sup>-6</sup>  |
|                                                                 | 12                   | 3                | 2 <sup>-10</sup>                  | 2 <sup>-10</sup> |
|                                                                 | 16                   | 4                | 2 <sup>-13</sup>                  | 2 <sup>-13</sup> |
|                                                                 | 20                   | 5                | 2 <sup>-17</sup>                  | 2 <sup>-15</sup> |
|                                                                 | 24                   | 6                | 2 <sup>-18</sup>                  | 2 <sup>-15</sup> |
| Sqrt <sup>(4)</sup>                                             | 4                    | 1                | 2 <sup>-7</sup>                   | 2 <sup>-7</sup>  |
|                                                                 | 8                    | 2                | 2 <sup>-14</sup>                  | 2 <sup>-14</sup> |
|                                                                 | 12                   | 3                | 2 <sup>-19</sup>                  | 2 <sup>-15</sup> |

1. The maximum residual error is the maximum error that performs the same calculation as a double-precision floating-point number after a given number of iterations. There may be additional rounding errors up to 2<sup>-16</sup> for the q15 format and 2<sup>-20</sup> for the q31 format.

2. For modulus greater than 0.5, the achievable accuracy decreases proportionally with the magnitude of the modulus, as the quantization error becomes significant.
3. SCALE = 1. If a higher scaling factor is used, the accuracy that can be achieved is proportionally reduced.
4. SCALE = 0. If a higher scaling factor is used, the accuracy that can be achieved is proportionally reduced.

#### 43.2.6 Zero-overhead mode

The fastest way to use a coprocessor is to pre-program the CORDIC\_CSR register, set the function to be executed (FUNC), the number of clock cycles required (PRECISION), the size of input and output values (ARGSIZE, RESSIZE), the number of input parameters (NARGS) and/or the number of results (NRES), and, if needed, set the scaling factor (SCALE). The calculation is then triggered by writing the input parameters to the CORDIC\_WDATA register. Once the correct number of input parameters have been written (and any ongoing calculations have been completed), a new calculation is started using these input parameters and the current CORDIC\_CSR settings. If there is no change, there is no need to reprogram the CORDIC\_CSR register.

If dual 32-bit input parameters are required (ARGSIZE = 0, NARGS = 1), the primary input parameter ARG1 must be written first and then the secondary input parameter ARG2. If the secondary parameters remain the same in a series of calculations, the second write can be avoided by reprogramming the number of parameters to one (NARGS = 0) after the first calculation has started. As long as the FUNC has not changed, the secondary argument retains its programmed value.

Note: After reset, ARG2 is set to +1 (0x7FFFFFFF).

If you use two 16-bit parameters (ARGSIZE = 1), you must package them into a 32-bit word, with ARG1 in the least significant half-word and ARG2 in the most significant half-word. The packed 32-bit word is then written to the CORDIC\_WDATA register. Only one write is required in this case (NARGS = 0).

For functions that take only one input parameter ARG1, it is recommended to set NARGS = 0.

If NARGS = 1, a second write to CORDIC\_WDATA must be performed to trigger the calculation. ARG2 data is not used in this case.

Once the calculation begins, any attempt to read the CORDIC\_RDATA register is inserted into the bus wait state until the calculation is complete, and then the result is returned. So the software can write the input and read the result immediately without polling to see if it's valid. Alternatively, the processor may wait for an appropriate number of clock cycles before reading the result. If desired, this time can be used to program the CORDIC\_CSR register for the next calculation and prepare the next input data. The CORDIC\_CSR register can be reprogrammed during the calculation without affecting the result of the ongoing calculation. In the same way, once the previous parameter is configured, the CORDIC\_WDATA register can be updated with the next parameter. The next parameter and settings take effect until the previous calculation is complete.

After the calculation is complete, the result can be read from the CORDIC\_RDATA register.

If two 32-bit results are required ( $NRES = 1$ ,  $RESSIZE = 0$ ), the primary result ( $RES1$ ) is read first, and then the secondary result ( $RES2$ ) is read. If only one 32-bit result is expected ( $NRES = 0$ ,  $RESSIZE = 0$ ), only the primary result ( $RES1$ ) needs to be read.

If a 16-bit result is required ( $RESSIZE = 1$ ), a single read of `CORDIC_RDATA` gets two results packed into a 32-bit word.  $RES1$  is located in the lower half word and  $RES2$  is located in the upper half word. In this case, it is recommended to program  $NRES = 0$ . If  $NRES = 1$ , a second read of `CORDIC_RDATA` must be performed in order to release `CORDIC` for the next operation. Data from the second read must be discarded.

If the expected number of parameters have been written, the next calculation begins after the expected number of results have been read. This means that at any time, there may be a calculation in progress, or waiting to read the result, and an action pending. When an operation is in the pending state, if `CORDIC_WDATA` is further accessed, the pending operation will be canceled and the related data will be overwritten.

The following sequence summarizes the use of `CORDIC` in zero overhead mode:

1. Set the `CORDIC_CSR` register.
2. Configure the parameters of the first calculation in the `CORDIC_WDATA` register. This will initiate the first calculation.
3. If necessary, update the `CORDIC_CSR` register to set the configuration for the next calculation.
4. Read the result from the `CORDIC_RDATA` register.
5. Configure the parameters for the next calculation in the `CORDIC_WDATA` register.
6. Go to step 3.

#### 43.2.7 Polling mode

The `RRDY` flag in the `CORDIC_CSR` register is set when there is a new result in the `CORDIC_RDATA` register. The flag can be polled by reading the register. Reset the `CORDIC_RDATA` register by reading it once or twice, depending on the  $NRES$  field of the `CORDIC_CSR` register.

When the result is read immediately when it is no longer available, polling the `RRDY` flag takes slightly longer than reading the `CORDIC_RDATA` register directly.

#### 43.2.8 Interrupt mode

By setting the interrupt enable (`IE`) bit in the `CORDIC_CSR` register, an interrupt is generated whenever the `RRDY` flag is generated. When the flag resets, the interrupt is cleared.

This mode allows the calculation result to be read under the interrupt service routine and therefore has a priority over other tasks. However, it is slower than reading results directly or polling flags due to interrupt processing delays.

#### 43.2.9 DMA mode

If the DMA write enable (`DMAWEN`) bit in the `CORDIC_CSR` register is set and there are no pending operations, a DMA write request is generated. The DMA controller can transfer the main input parameter (`ARG1`) to the `CORDIC_WDATA` register.

If  $NARGS = 1$  in the `CORDIC_CSR` register, a second DMA write request is generated to transfer the auxiliary input parameter (`ARG2`) into the `CORDIC_WDATA` register. When all input parameters have

been written, and any ongoing calculations have been completed (by reading the results), a new calculation is started and another DMA write request is generated.

If the DMA Read Enable (DMAREN) bit in the CORDIC\_CSR register is set, a DMA read request is generated when the RRDY flag is set. The DMA controller can then read the primary result (RES1) from the CORDIC\_RDATA register. If NRES = 1 in the CORDIC\_CSR register, a second DMA request is generated to read out the auxiliary result (RES2). When all results have been read, the RRDY flag is cleared. Note: Since DMA performs access to the CORDIC\_WDATA or CORDIC\_RDATA register, each DMA request must be acknowledged. Therefore, when DMA read is enabled, the CPU must be prevented from accessing the CORDIC\_RDATA register. Similarly, the processor must avoid accessing the CORDIC\_WDATA register when DMA write is enabled.

### 43.3 TIMx registers

The register width is 32 bits.

#### 43.3.1 CORDIC Control/Status Register (CORDIC\_CSR)

## 44. 6800/8080 Controller (LCDC)

### 44.1 Overview

The LCDC is used to drive the 8080/6800 protocol LCD display.

The LCDC module has the flexibility to write instructions/data to and read data from the LCD display.

The LCDC module can configure the timing of read/write operations separately (the duration of read/write drive pulses can be configured separately) to adapt to different LCD displays.

### 44.2 Main features

- Programmable read-write pulse width
- Supports 8080/6800 LCD displays with data bit width less than or equal to 18 bits, including common data bit widths such as 8/9/16/18
- Supports driving up to 4 LCD displays (in time division multiplexing mode), and the timing parameters of the 4 displays, the protocol can be configured separately
- Reading and writing to a data register is equivalent to reading and writing to an LCD
- Supports massive data writing to LCD using DMA without consuming CPU resources

### 44.3 Functional description

#### 44.3.1 Enable the LCDC

The EN0-3 bits of the LCDC\_CSR are written by 1, that is, LCD0-3 are enabled; When 0 is written to EN0 to 3 bits of the LCDC\_CSR, LCD0 to 3 are disabled.

If the LCDC is in a disabled state, writing data to the LCDx\_DR/LCDx\_CMDR (x = 0-3) register does not trigger a write data/instruction operation to the LCD, data read from the LCDx\_DR register is an invalid value, and does not trigger a read data operation to the LCD.

Control logic of CS signal line (chip selection line): When LCDx is working, CSx is at low level (at this time, other CS lines are at high level), and when LCDx is not working, CSx is at high level.

#### 44.3.2 Operating mode

When the MODEx bit of LCD\_CSR is 1, LCDx operates in 6800 mode, otherwise it is 8080 mode. After reset, the LCDx works in 8080 mode by default.

#### 44.3.3 Send LCD data

If LCDx is in the enabled state, you only need to write the LCDx\_DR register to trigger LCDx data sending. PinLCDC\_RSishigh, and D [17: 0] will be recognized as data.

When reading and writing LCDx\_DR, timing parameters will be configured according to LCDx\_WCFGR (write operation) and LCDx\_RCFGR (read operation).

When the LCD is enabled and the DMA mode is enabled, if the LCDC does not transmit data, it will send a write request to the DMA, and if the DMA responds to the write request, the LCDC will take the data sent from the DMA as LCD write data and send it to the pin. While the LCDC is transmitting data, the LCDC will stop sending write requests.

#### 44.3.4 Send LCD command

If LCDx is in the enabled state, you only need to write the LCDx\_CMDR register to trigger the LCDx instruction sending. Pin LCD\_C\_S is low, and D[17:0] will be recognized as the instruction.

When reading and writing LCDx\_CMDR, timing parameters will be configured according to LCDx\_WCFGR (write operation) and LCDx\_RCFGR (read operation).

If LCDx is enabled, you only need to read the LCDx\_DR register to read the LCD display.

#### 44.3.5 Read instructions from LCD

LCDC supports read instruction operation. When LCDx is in the enabled state, it only needs to read the LCDx\_CMDR register to trigger the LCDx instruction read. Different from data reading, when reading the instruction, the pin LCD\_C\_S is low.

Note: Some models of LCDs can read the device ID or status register directly in this way without writing instructions in advance.

#### 44.3.6 LCDC timing

##### (1) LCDx 8080 write data/instruction timing

When LCDx\_DR is written, an 8080/6800 write data operation is triggered; When LCDx\_CMDR is written, an 8080/6800 write command operation is triggered. If the LCD\_CSR register MODEx = 0, the 8080 timing is triggered, otherwise, the 6800 timing is triggered.

When the LCDC module is writing data/commands to the LCD, busy = 1, any register of the LCDC cannot be written during this period, otherwise the write data will be ignored. Read LCDC\_CSR [17] to know the busy state.

The LCDC\_WR in the picture above is the LCDC\_8WR\_6E pin of the microprocessor; LCDC\_RD is the LCDC\_8RD\_6RW pin of the microprocessor.

## (2) LCDC 8080 Read Data/Instruction Timing

When **LCDx\_DR** is read, an 8080/6800 data read operation is triggered; When **LCDx\_CMDR** is read, an 8080/6800 read command operation is triggered. If the **LCD\_CSR** register **MODEx = 0**, the 8080 timing is triggered, otherwise, the 6800 timing is triggered.

When the LCDC module reads data from the LCD, the APB bus cannot access any registers of the LCDC.

The **LCDC\_RD** in the picture above is the **LCDC\_8RD\_6RW** pin of the microprocessor; **LCDC\_WR** is the **LCDC\_8WR\_6E** pin of the microprocessor.

## (3) LCDC 6800 write data/instruction timing

The trigger mode is the same as 8080, and the **LCD\_CSR** register **MODEx = 1** needs to be set.

The **LCDC\_E** in the picture above is the **LCDC\_8WR\_6E** pin of the microprocessor; **LCDC\_RW** is the **LCDC\_8RD\_6RW** pin of the microprocessor.

#### (4) LCDC 6800 Read Data/Instruction Timing

The trigger mode is the same as 8080, and the LCD\_CSR register MODEx = 1 needs to be set.

The LCDC\_E in the picture above is the LCDC\_8WR\_6Epin of the microprocessor; LCDC\_RW is the LCDC\_8RD\_6RWpin of the microprocessor.

#### 44.3.7 DMA request

After the DMA responds to the LCDC transfer request, it will send write data to the LCDC register, and the LCDC starts sending data.

##### (1) Peripheral address

The DMA function is only used for write data of LCD0\_DR to LCD3\_DR. Sending instructions, instruction parameters, and timing parameters must be used by CPU.

##### (2) Data width

The LCDC module supports DMA transmission of bytes, half words and words. In the LCDC registers, LCD0\_DR ~ LCD3\_DR support byte, half-word, and word writing, while the other registers only support word writing.

When DMA or CPU writes half-word data to LCDx\_DR, pin LCDC\_D [17:16] will send low level; When DMA or CPU writes byte data to LCDx\_DR, pin LCDC\_D [17: 8] sends low.

##### (3) Scope of application

The DMA of the LCDC has only write requests and no read requests. When reading data, it will occupy CPU resources for a long time.

When the DMA transmission is not complete, the CPU cannot access any registers of the LCDC, and the LCDC action cannot be guaranteed.

LCDC only supports 1 DMA transmission. When LCDC turns on DMA transfer, it does not support multiple DMA channels to write to LCDC, nor does DMA write to multiple LCDC registers.

#### 44.3.8 LCDC busy mechanism

When the LCD is transmitting data (read or write data/instructions), the LCDC will be busy, LCD\_CSR [17] = 1 (the busy bit is equal to 1).

When the LCD is in the busy state, no write operation is allowed in any register of the LCDC, otherwise the write data will be ignored.

If the CPU accesses LCDx\_DR/LCDx\_CMDR, when the LCD is in the busy state, the data register LCDx\_DR is not allowed to be read, otherwise the read data is fixed to 0, but the LCDC\_CSR, LCDx\_WCFGR, LCDx\_RCFGR registers are allowed to be read.

## 44.4 TIMx registers

Note: Only LCD0\_DR ~ LCD3\_DR support byte, half-word, and word writing, and the rest of the registers only support word writing. All registers support word reading only.

## 45. MCU debugging interface

### 45.1 Introduction

The MCUIDBG module provides debuggers with the following support:

- Low-power modes
- Clock control for timers, watchdogs, I2C and CAN
- The MCUIDBG register also provides the encoding of the chip ID. This ID encoding can be accessed by a JTAG or SW debug interface, or by a user program.

### 45.2 Main features

- Supports debugging of sleep mode, stop mode and standby mode
- When the CPU enters the HALT mode, the control timer or watchdog stops counting or continues counting
- Prevent I2C's SMBUS timeout when CPU enters HALT
- Disable modification function when reading of CAN is enabled

### 45.3 Functional description

#### 45.3.1 Support debugging low power mode

The user can enter the low power mode by executing the WFI and WFE instructions.

The MCU supports a variety of low-power modes, which can turn off the CPU clock or reduce CPU power consumption.

The kernel does not allow FCLK or HCLK to be turned off during debugging. As these are required for the debugger connection, during a debug, they must remain active. The MCU uses a special way that allows users to debug code in low power mode.

To achieve this function, the debugger must first set some configuration registers to change the characteristics of low power mode.

- In sleep mode, the debugger must first set the DBG\_SLEEP bit. This will provide HCLK with the same clock as FCLK.
- In stop mode, the debugger must first set the DBG\_STOP bit. This will activate the HSI16 clock, providing clocks for FCLK and HCLK in stop mode.
- Instandby mode, the debugger must first set the DBG\_STDBY bit. This will activate the HSI16 clock, providing clocks for FCLK and HCLK in standby mode.

## 45.4 TIMx registers

The MCUIDBG register is mapped on the external PPB bus.

### 45.4.1 ID coding (DBGMCU\_IDCODE)

The register is reset by power-on, and the system reset does not reset the register. When the kernel is in the reset state, the debugger can access this register.

Address offset: 0x00

Reset value: 0x4444BBBB

### 45.4.2 Debug Configuration Register (DBGMCU\_CR1)

The register is reset by power-on, and the system reset does not reset the register. When the kernel is in the reset state, the debugger can access this register.

Address offset: 0x04

Reset value: 0x0000\_0000

| 2    | DBG_STDBY     | RW | 0 | Debug standby mode.<br>0: (FCLK off, HCLK off) Normal standby mode processing;<br>1: (FCLK ON, HCLK ON) The system clock is supplied by HSI 16. The MCU automatically generates a system reset to exit standby mode, which is the same as the power-on reset.                                                                                                                                                                                                                                                                                                         |
| 1    | DBG_STOP      | RW | 0 | Debug Stop mode<br>0: (FCLK OFF, HCLK OFF) In stop mode, both HCLK and FCLK are off. When exiting from stop mode, the clock configuration is the same as after reset (system clock is HSI16). Subsequently, the software needs to reconfigure the clock controller to enable the PLL and HSE, etc.<br>1: (FCLK=On, HCLK=On). When entering the stop mode, the internal clock source of the system will not be turned off, and FCLK and HCLK exist. When exiting Stop mode, the software must reprogram the clock controller if the clock control needs to be changed. |
| 0    | DBG_SLEEP     | RW | 0 | Debugging sleep mode.<br>0: (FCLK ON, HCLK OFF). In Sleep mode, FCLK is provided by the previously configured system clock, and HCLK is turned off. Since sleep mode does not reset the configured clock system, the software does not need to reconfigure the clock after exiting sleep mode.<br>1: (FCLK=On, HCLK=On). In sleep mode, both the FCLK and HCLK clocks are provided by the previously configured system clock.                                                                                                                                         |

#### 45.4.3 Debug Configuration Register (DBGMCU\_CR2)

The register is reset by power-on, and the system reset does not reset the register. When the kernel is in the reset state, the debugger can access this register.

Address offset: 0x08

Reset value: 0x0000\_0000
